Plenary I: AEESP Lecture

From Particle Counting to Aerosol Collection: Just Add Water. SUSANNE HERING, *Aerosol Dynamics Inc.*

Ultrafine, airborne particles are important in the atmosphere, and in some industrial processes. Yet direct measurement is difficult, as most are too small to detect optically, or to collect inertially. Since the nineteenth century, aerosol scientists have circumvented this issue using condensational growth to enlarge ultrafine particles. Today, applications extend from number concentration measurements, to collection for chemical analysis, to aerodynamic concentration for mass spectrometry or exposure studies.

Although the original, adiabatic expansion methods of Aitken and Courtier used water as the condensing species, the more wide-spread method since the 1970s has been laminar-flow, alcohol-based condensational growth. The continuous flow and single particle counting capability of these methods is important to many applications, but the alcohol is not always suitable. The desire to return to water as the condensing material, without sacrificing the advantages of the alcohol systems, motivated the development of the laminar-flow water condensation particle counter (water-CPC). The challenge is the high diffusivity of water vapor. The water-CPC reverses the temperatures of the laminar flow alcohol instruments, with a cold saturator followed by a warm, wet-walled condenser. This approach recognizes that condensation is not created by a cold region, but rather is a result of the relative rates of thermal and vapor diffusion. Water, being the smaller molecule, has a mass diffusivity that is larger than the thermal diffusivity of air. As a cooled flow enters the warm, wet walled region, both heat and water vapor diffuse into the flow; yet the water vapor wins the race, creating a region of high supersaturation along the centerline. This approach readily activates condensational growth at 5 nm. However, as originally implemented, the output flow that is warm and humid, forcing optics to be operated at elevated temperature, and compromising volatile species collected for chemical analysis.

A new, “moderated” approach eliminates the warm, humid output flow. The uniformly warm, wet-walled condensing region of the original approach is replaced by a short, warm wet-walled, “initiator” section followed by a somewhat longer cold, “moderator” section. Once the vapor supersaturation is created within the wet-, warm-walled initiator region, the saturation profiles are insensitive to the temperature of the walls downstream. The subsequent moderator section can be operated the same temperature as the initiator (as done in the first water-CPCs), or at a colder temperature, with no affect on the peak supersaturation. But with the cold moderator the temperature and dew point of the output flow are below 20°C, and non-condensing at typical room temperature.

This “moderated” method opens the door to many additional applications. It is possible to collect ambient aerosol in a concentrated, dry 1-mm diameter spot without heating the sample above ambient temperatures. The approach can be used for directly imaging particles within a mobility separation column, without fogging the optics, enabling fast size distributions, or rapid determination of hygroscopic growth. With the moderated approach, the output temperature is not longer coupled the temperature of the warm initiator section, and thus the system can be operated at high temperature differences between the first two stages, enabling the detection of particles in the 1-2 nm size range. Moreover, it possible to control the output relative humidity to the same value as the that of a conditioned sampled air stream, creating a reservoir-less system that operates for weeks without replenishing the wick. Collection and counting can be combined in a single unit – making self-sustaining condensation counter-collector, such that every particle once counted is deposited on a small substrate that may be removed for microscopic or micro-chemical analysis. These are some of the various applications of water-based condensational growth to aerosol measurement.

Keywords: nanoparticle, condensation particle collector, electrical charging, particle imaging

Industrialization of Fine-Particle-Based “Products by Process” to Enable Demanding Customer Applications. YAKOV KUTSOVSKY, *Cabot Corporation*

Over the last 150 years, aerosol-produced fine particles have been used to enable key everyday applications – newspaper printing and reinforcement of tires with carbon black, chemical mechanical polishing of silicon wafers and silicone reinforcement with fumed metal oxides. In contrast, current trends in modern society require vehicle light-weighting and electrification, digital ink jet printing and 3D additive manufacturing. These trends place high demands on new materials that need to deliver key performance attributes as well as scaled manufacturing to allow the appropriate cost-in-use in the applications.

Development and scale-up of particles with the desired application performance attributes bring product and process needs together to define the concept of “product by process” - materials characteristics and performance that are defined by the particle production process and scale. This presentation will introduce this concept and will provide several examples of how it is applied in development of new products for tires and energy materials applications. These developments show that the connection between application needs and a deep understanding of material properties to deliver them can enable new innovations in century old technologies.

In addition to expanding opportunities with existing classes of materials such as carbon blacks we are advancing process and applications technologies with advanced carbon materials - graphenes and carbon nanostructures. These materials require a holistic approach spanning safe production and uses of these materials to finding ways to incorporate them into customer applications to deliver breakthrough performance. Examples to illustrate these points will be shared in the presentations.

Plenary III

High Sectorially Resolved Inventories to Evaluate Air Quality Trends in China. SHU TAO, *Peking University*

Based on a set of high-sectorially resolved air pollutant emission inventories, impacts of socioeconomic transition and regulations on air pollution allevation in China were evaluated. Three case studies are presented to illustrate the lessons learned: 1) Impact of rural residential energy transition on air pollution and health; 2) Health effects of banning beehive coke ovens; and 3) Effectiveness of recent emission reduction efforts of major cities.

Rural household energy use is an important source of emission of air pollutants in China. However, the magnitude of rural household energy use, especially during the transition from use of solid fuels to clean fuels and electricity, has not been well quantified. To collect first-hand data on rural energy consumption and transition, the nationwide data were collected from a 34,489-household energy mix survey and a 1670-household fuel weighing campaign. It was found that the previous information from the International Energy Agency (IEA) and Food and Agriculture Organization (FAO) had significant errors. Consumption of wood and crop residue decreased by 61% and 57%, respectively, from 1992 to 2012 in rural China, much higher than the 15% and 8% reported by IEA and FAO. The fast energy transition that China is experiencing, primarily driven by an increase in income, has resulted in a significant emission reduction and health-climate co-benefit. It was estimated that the relative contribution of the rural residential sector to exposure to ambient PM2.5 decreased from 18±13 to 14±10 mg/m^3, that premature deaths decreased from 390 (360-420 as semi-quartile range) to 220 (200-250) thousand, and climate forces decreased from 0.057 ± 0.016 to 0.031 ± 0.008 W/m^2 during a period from 1992 to 2012, respectively. Still, the dependency of rural residents in northern China on traditional biomass and coal for heating is one of the most important factors contributing to ambient PM2.5 associated health outcomes.

Althoiugh beehive coke ovens, which was a major souce of benzo[a]pyrene, were banned by the Coal Law in 1996, they were not totally eliminated till 2011. The heath effects of historical beehive coke oven operation, the health benefits of the ban, and the adverse impacts of the poor implementation of the ban were quantitatively evaluated. Historical emissions of benzo[a]pyrene were re-constructed based on satellite images and used to model atmospheric transport, non-occupational population exposure, and induced lung cancer risk. It was demonstrated that more than 20% of the benzo[a]pyrene in ambient air was from beehive coke production in the peak production year. The cumulative non-occupational excess lung cancer cases associated with benzo[a]pyrene from beehive coke ovens was 3,500 (±1,500) from 1982 to 2015. If there was no ban, the cases would be as high as 9,290 (±4,300), indicating significant health benefits of the Coal Law. If the ban had been fully implemented immediately after the law was enforced in 1996, the cumulative cases would be 1,500 (±620), showing the importance of implementing the law.

Measures have been taken to reduce PM2.5 concentrations in China. However, the effectiveness of these measures has not been evaluated. To do so, confunding effects of meteorological factos have to be eliminated. A novel approach is applied to address this issue by individually quantifying the influences of emissions and meteorological effects on PM2.5 concentrations.Ambient PM2.5 concentrations from 1980 to 2014 were modeled subjected to three conditional scenarios that included a realistic situation, fixed emissions, and fixed meteorology. The differences among the model outputs were analyzed to quantify the relative contributions of emissions and meteorological factors. The output from the fixed-meteorology simulation was applied to develop regression models to predict emissions-driven PM2.5 concentrations, whereas the output from the fixed-emission simulation was adopted to establish probability functions to characterize the meteorological factor-induced PM2.5 fluctuations. The models were used to assess the effectiveness of the emissions reduction efforts implemented in major Chinese cities. It is demonstrated that the current decreasing PM2.5 trends in major Chinese cities are primarily driven by mitigation efforts, whereas the rebounds occasionally occurred due to the meteorological effects. Targeted emission reduction objectives of majority of cities have been exceeded so far. If the targeted emissions reduction goals can be fully achieved, the annual mean PM2.5 concentrations in 73% (55-89% as the 95% uncertainty interval) of the 190 major cities would reach the national standard of 35 μg/m^3 by 2030, and the percentage would be 94% (85-98%) if 50% extra efforts are made.

Plenary IV

Improvement of Inhalation Toxicity Testing for Nanomaterials and Compliance Monitoring for Ambient PM. Jun Kanno, Chuen-Jinn Tsai, *Japan Bioassay Res. C. Kanagawa; Natl. Chiao-Tung U., Taiwan*

For the new nanomaterials (NM), in general, there is no pre-existing knowledge to suggest its toxicity. Therefore, whole-body inhalation toxicity study is the first choice considering the most important route of exposure to humans. Yet, “inhalation” is a big hurdle for toxicologists; facilities are expensive to build and run, and requires skillful operators. Methods to generate well-dispersed aerosol and quantitate the aerosol density require case-by-case innovation, which is costly and time consuming. In order to overcome such hurdles, we developed the “Taquann” dispersion method and a “direct injection” whole body inhalation system. The dispersion method is based on two concepts: liquid-phase fine filtration and critical point drying to avoid re-aggregation by surface tension. Briefly, the bulk sample is suspended and dispersed in tert-butyl alcohol, filtered by a fine mesh to remove aggregates/agglomerates, snap-frozen by liquid nitrogen, and vacuumed, mimicking the process of critical point drying. Then aliquots of dry dispersed sample are periodically injected to the chamber system by the compressed air to maintain the aerosol concentration in the exposure chambers. This method is shown to be applicable to Mitsui-7 and Nikkiso MWCNTs, three different makes of nano-TiO_2, potassium titanate whiskers, and others. The advantages of this system is its cheapness and easy operation, high adjustability to various NM samples, low chance of polluting the facility, and low loss of sample. We believe our new system makes inhalation studies much popular to facilitate the risk assessment of not only various new NMs but also any other particulate matters including $PM_{2.5}$ from various origins.

While NM risk assessment is conducted *in vivo* or *in vitro*, most epidemiological studies link human health impacts to $PM_{2.5}$ mass measured at ambient environment. FRM $PM_{2.5}$ samplers and FEM monitors are used as compliance monitors, which make use of size-selective inlets followed by a filter to collect particles for further analysis. However, $PM_{2.5}$ concentrations determined by the FRM samplers are not true concentrations due to the uncertainties in the evaporation loss of volatile aerosol materials and water associated with aerosols during aerosol sampling and conditioning. The differences between $PM_{2.5}$ FEM and FRM concentrations often exist and increase with decreasing $PM_{2.5}$ concentrations. This talk will address the improvement in PM_{10} and $PM_{2.5}$ inlets, and aerosol conditioning during filter sampling which results in true $PM_{2.5}$ concentrations. The US EPA PM_{10} inlet and $PM_{2.5}$ inlet, including the well impactor ninety-six (WINS) and the very sharp cut cyclone (VSCC) were found to have particle bounce or particle overloading problems, which change the cutoff characteristics and PM concentrations. The grease-coated substrate of the PM_{10} inlet was replaced by an oil-soaked glass fiber filter to capture particles effectively. The impaction surface of the $PM_{2.5}$ WINS was re-designed to allow a small amount of water or vacuum oil to inject upward to wash deposited particles off the plate. The modified PM inlets eliminated particle bounce and particle overloading effectively with small errors during long-term sampling. A chilled filter sampler followed by a Nafion dryer was found to suppress the evaporation loss of semi-volatile inorganic materials (SVIM) effectively due to a small amount of water vapor condensation during sampling and conditioning processes. The total evaporation loss of SVIM in $PM_{2.5}$ measured by chilled filter sampler was effectively reduced and the accuracy of $PM_{2.5}$ sampling was significantly improved after correcting for the amount of condensed water determined empirically. These improvements lead to accurate PM data that can be related to health effects meaningfully and used to calibrate widely used low-cost PM sensors reliably.

Keywords: MWNT, nanomaterials, inhalation toxicity, aerosol sampling, PM inlet, $PM_{2.5}$.

Plenary V

On the Thermodynamics and Kinetics of Atmospheric Aerosol Formation. ILONA RIIPINEN, *Stockholm University*

The conversion of atmospheric vapors to aerosol particle and cloud hydrometeor populations depends on one hand on the energetics of the condensed phase, and on the other hand on the kinetics of the gas-phase molecules and particle populations. These thermodynamic and kinetic aspects are intertwined in aerosol formation processes, and generally difficult to isolate from field observations or even well specified laboratory data. Theoretically robust process models that accurately account for the kinetics and thermodynamics of aerosol formation are therefore critical for interpreting empirical data. The combination of such theoretical tools with experimental data on atmospherically relevant environments and molecules is the key for provide generalizable approaches to predict aerosol formation in e.g. climate and air quality models. In my presentation, I will summarize recent advances in understanding the key thermodynamic and kinetic features of aerosol formation, and discuss remaining key uncertainties in our efforts of creating approaches for describing aerosol formation with predictive power in various atmospherically relevant conditions.

1AC.1
Understanding Missing Sources of Fine Particulate Organosulfur Compounds in the Atmosphere: Implications from Ambient Measurements and Laboratory Experiments. MATTHIEU RIVA, Yuzhi Chen, Lindsay Yee, Hilary Green, Tianqu Cui, Nicole Olson, Nancy Ziying, Karsten Baumann, Mike Fort, Eric Edgerton, Eladio Knipping, Stephanie L. Shaw, Sri Hapsari Budisulistiorini, Caitlin Rose, Zhenfa Zhang, Avram Gold, Barbara Turpin, William Vizuete, Igor O. Ribeiro, Santos e Oliveira, Cristine Machado, Sérgio Duvoisin Junior, Rodrigo A. F. de Souza, Eliane Gomes, et al., *University of North Carolina at Chapel Hill*

Organosulfur compounds are ubiquitous in Earth's atmosphere. These compounds are non-negligible contributors to fine organic aerosol mass. Among them, sulfate esters or organosulfates (OSs) contribute the greatest mass fraction of particulate organosulfur compounds. These aerosol constituents are formed from multiphase chemical processes, such as the acid-catalyzed reactive uptake of gas-phase products generated from the atmospheric oxidation of biogenic and anthropogenic volatile organic compounds (VOCs) in the presence of aqueous sulfate aerosols. While the presence of OSs has been reported in fine aerosol collected from many locations, especially in biogenic-rich areas, the impacts of such products on the physicochemical properties of and the sulfate distribution within secondary organic aerosol (SOA) remain unclear. As sulfate over continental regions is generally of anthropogenic origin or from the oxidation of dimethyl sulfide, understanding the physical and chemical processes associated with SOA formation and properties, and how sulfate impacts them is crucial to properly representing SOA in models and evaluating their impacts on climate and human health.

SOA samples collected from the southeastern U.S. and the Amazon forest (isoprene and monoterpene-dominated atmospheres), were chemically characterized to evaluate the distribution of fine particulate organosulfur compounds. OSs and methanesulfonic acid (MSA) were quantified by ultra-performance liquid chromatography interfaced with electrospray ionization high-resolution quadrupole time-of-flight mass spectrometry (UPLC/ESI-HR-QTOFMS). Total organosulfur mass was determined by isotope ratio inductively coupled plasma mass spectrometry. OSs were found to contribute significantly to the organic aerosol (OA) mass in both areas. Total quantified OSs plus MSA, however, only accounted for about 50% of total organosulfur, suggesting the presence of a significant amount of unidentified organosulfur chemicals of different functionality, and unidentified processes that form them. We hypothesize that the missing mass is comprised of sulfate-containing oligomers formed from multiphase chemistry of BVOC oxidation products, especially the isomeric isoprene epoxydiols (IEPOX), with acidic sulfate aerosols. Targeted atmospheric simulation chamber experiments re-investigating the multiphase chemistry of IEPOX revealed that formation of OSs cannot fully account for the amount of sulfate consumed, suggesting that the missing source of organosulfur compounds can arise from previously uncharacterized IEPOX chemistry. Overall, our findings provide a comprehensive picture of particle-phase processing governing isoprene-derived SOA composition and suggest the role of IEPOX-OSs in SOA evolution has previously been underestimated.

1AC.2

Importance of Sulfate Radical Anion Formation and Chemistry in Heterogeneous OH Oxidation of Organosulfates. Kai Chung Kwong, Man Mei Chim, James F. Davies, Kevin Wilson, MAN NIN CHAN, *The Chinese University of Hong Kong*

Organosulfates are important organosulfur compounds present in atmospheric particles. While the abundance, composition, and formation mechanisms of organosulfates have been extensively investigated, it remains unclear how they evolve throughout their atmospheric lifetime. To acquire a fundamental understanding of how organosulfates chemically transform in the atmosphere, this work investigates the heterogeneous OH radical-initiated oxidation of sodium methyl sulfate droplets, the smallest organosulfate detected in atmospheric particles, using an aerosol flow tube reactor at a high relative humidity of 85 %. Aerosol mass spectra measured by a soft atmospheric pressure ionization source (Direct Analysis in Real Time, DART) coupled with a high-resolution mass spectrometer showed that neither functionalization nor fragmentation products are detected. Instead, the ion signal intensity of the bisulfate ion has been found to increase significantly after OH oxidation. We postulate that sodium methyl sulfate tends to fragment into a formaldehyde and a sulfate radical anion ($SO_4^{\bullet-}$) upon OH oxidation. The formaldehyde is likely partitioned back to the gas phase due to its high volatility. The sulfate radical anion can abstract a hydrogen atom from neighboring sodium methyl sulfate to form the bisulfate ion, contributing to the secondary chemistry. Overall, the heterogeneous OH oxidation of an organosulfate can lead to the formation of $SO_4^{\bullet-}$ and produce inorganic sulfate. Fragmentation processes and sulfate radical anion chemistry play a key role in determining the compositional evolution of sodium methyl sulfate during heterogeneous OH oxidation.

1AC.3

α-Hydroxy Organosulfates and Nitroxy Organosulfates Derived from Monoterpenes: Stability and Ambient Presence.

Yuchen Wang, Rongbiao Tong, JIAN ZHEN YU, *Hong Kong University of Science & Technology*

Organosulfates (OSs) derived from biogenic volatile organic compounds represent an important class of products formed between anthropogenic sulfur pollution and natural emissions. A lack of commercially available OS standards presents a significant obstacle to quantify this chemical interaction between human and nature. We synthesized α-hydroxy OS standards derived from eight monoterpenes (i.e., α- & β- pinene, limonene, sabinene, Δ3-carene, terpinolene, α-terpinene, and γ-terpinene) and two sesquiterpenes (i.e., α-humulene and β-caryophllene). After comparison of the MS/MS spectra and liquid chromatographic retention times between standards and ambient aerosol, we have positively identified α-hydroxy OSs derived from six monoterpenes (i.e., α- & β-pinene, limonene, sabinene, Δ3-carene, and terpinolene), and β-caryophllene in ambient samples from select locations in China, but failed to detect α-hydroxy OSs derived from α-terpinene, γ-terpinene, or α-humulene. With the exception of α-pinene, we did not detect OS regioisomers that have the sulfate group at the more substituted carbon position. This observation may have implication on OS formation mechanism, appearing to favor a diol intermediate pathway. Nitroxy organosulfates derived from limonene and β-pinene were also synthesized, providing opportunities to study their stability. Our work highlights the critical importance of having authentic standards in advancing our understanding of organosulfates.

1AC.4

Experimental Study of Condensed-Phase Reaction Kinetics of Secondary Organic Aerosols from Isoprene Expoxydiols.

YUZHI CHEN, Matthieu Riva, Theran P. Riedel, Havala Pye, Nicole Olson, Ziying Lei, Zhenfa Zhang, Avram Gold, William Vizuete, Barbara Turpin, Andrew Ault, Jason Surratt, *University of North Carolina at Chapel Hill*

Isoprene epoxydiols (IEPOX), OH-initiated oxidation products of isoprene, are known to produce secondary organic aerosol (SOA) through acid-catalyzed heterogeneous reactions in the presence of sulfate-containing aerosols within the atmosphere. IEPOX-derived SOA can contribute up to 40% of summertime organic aerosol mass in isoprene-rich regions like the southeastern U.S. Among all SOA tracers identified during laboratory and field studies, 2-methyltetrols and 2-methyltetrol sulfate esters, also referred to as IEPOX-derived organosulfates (OSs), together contribute a major mass fraction (e.g. >90% at Look Rock, TN) of IEPOX-derived SOA. Regulatory models that adopt rate constants for the formation of these two species from kinetic measurements in bulk solutions, however, typically yield discrepancies between model predictions and observations suggesting a need for more accurate reaction-rate constants with sulfate-containing aerosols. Non-ideality of aerosols may affect the applicability of kinetic measurements from bulk solution studies. While computational estimates of the reaction-rate constants that took into account the non-ideality of aerosols were, on average, 2-3 orders of magnitude higher than those derived from measurements in bulk solutions (especially for IEPOX-derived OSs), and seemed promising to improve the model representation of IEPOX uptake process, supporting laboratory measurements are still lacking. We have developed an alternative approach that couples chamber experiments with offline chemical characterization and modeling to derive condensed-phase reaction-rate constants in IEPOX-derived SOA. These previous experiments, however, were conducted under only dry conditions (RH <5%) limiting our ability to extend the derived reaction-rate constants to more humid conditions. In addition, the lack of time-resolved reaction profiles of 2-methyltetrols and IEPOX-derived OSs and the potential for artifacts induced by filter collection also introduce uncertainties in the reaction-rate constants derived from the previous study.

In this work, chamber experiments were conducted using gaseous IEPOX and acidic sulfate aerosols to generate IEPOX-derived SOA in the UNC indoor chamber facility. Chamber-generated IEPOX-derived SOA samples were collected by a particle-into-liquid sampler (PILS) using a 5-minute time resolution. PILS samples were immediately analyzed by ion chromatography (IC) for inorganic constituents and ultra-performance liquid chromatography interfaced to high-resolution quadrupole time-of-flight mass spectrometry equipped with electrospray ionization (UPLC/ESI-HR-QTOFMS) for IEPOX-derived SOA tracers. Our results show that up to 90% of the inorganic sulfate was converted to IEPOX-derived OSs and oligomers in acidified ammonium sulfate particles within one hour of reaction with gas-phase IEPOX. Our results further demonstrate that the rates of IEPOX-derived OS formation were likely underestimated by prior bulk-solution kinetic studies. New condensed-phase reaction-rate constants for the formation of the 2-methyltetrols and IEPOX-derived OSs were derived from a one-dimensional box model of our chamber experiments using characterized reaction profiles resolved by PILS-IC and PILS-UPLC/ESI-HR-QTOFMS. The impacts of new reaction-rate constants on aerosol acidity and atmospheric formation of IEPOX-derived SOA need to be further assessed with updated air quality and global models, which is critical in understanding the governing processes that lead to SOA formation and developing air-pollution mitigation strategies.

1AC.5

Photochemical Multiphase Organonitrate Formation in Wet Particles Under Humid NOx Conditions. YONG LIM, Jihoon Seo, Jin Young Kim, Bong Kim, Barbara Turpin, *KIST*

NOx plays an important role in urban atmospheric chemistry. NOx, which is emitted from the fossil fuel combustion, affects secondary aerosol formation. Traditionally, NOx is known to be associated with gas-phase reactions forming semi-volatile products like organonitrates or ammonium nitrates, leading to secondary aerosol. Here, we discover organonitrate formation in the aqueous phase. We have conducted chamber experiments for photooxidation of wet aerosols containing glyoxal and ammonium sulfates under humid NOx conditions, and analyzed the products using high resolution quadrupole time of flight mass spectrometry (HR-Q-TOF-MS) and a scanning mobility particle sizer (SMPS). Nitric acid is dominantly formed by photooxidation of NOx and taken up into neutral wet particles substantially, resulting in dramatic hygroscopic growth at high relative humidity. In turn, increased aerosol liquid water in wet particles facilitates aqueous-phase reactions of glyoxal and dissolved nitric acid leading to organonitrate formation. We have identified several types of organonitrates formed by the reaction of glyoxal and nitric acid in the aqueous phase. We have also conducted the quantitative analysis for organonitrates by preparing standard solutions of glyoxal, nitric acid, and organonitrates from glyoxal-nitric acid mixtures with known concentrations. Using a thermodynamic model and a kinetic/equilibrium model based on smog chamber results, we have simulated ambient particle components (particularly, nitrates, organics and organonitrates) and particle acidity during the haze event at Seoul, the most urbanized city in South Korea, which is characterized by high NOx and relative humidity. HNO3 uptake into the particles and the hygroscopic growth and acidification of the particles were significant, and notably organonitrates were formed significantly. Our finding of organonitrate formation in the aqueous phase provides a new insight of secondary organic aerosol, enhancing our understanding and model predictions for organic particles, whose formation is still not well explored.

1AC.6

Quantifying the Hydrolysis Rate of Daytime and Nighttime Organic Nitrates in Aerosol Water. MASAYUKI TAKEUCHI, Thomas Berkemeier, Gamze Eris, Nga Lee Ng, *Georgia Institute of Technology*

Ambient field studies have observed a varying level of atmospheric gaseous and particulate organic nitrates across different continents and many found that their contribution to fine organic aerosol mass is substantial. Depending on the fate, these organic nitrates could act as a reservoir and/or permanent sink of reactive oxidized nitrogen species (i.e. NO_x), which eventually determines the production potential of tropospheric ozone. Modeling results using recent field measurement data in the Southeastern U.S. suggest that the lifetime of submicron particulate organic nitrates is on the order of several hours, though the loss mechanism is not known. Due to their direct impact on the NO_x cycling, ozone and secondary organic aerosol (SOA) formation, it is crucial to understand the dominant loss mechanisms of organic nitrates in the atmosphere and parameters that affect the loss rate. Among various loss mechanisms, particle-phase hydrolysis is a known loss mechanism of particulate organic nitrates in the presence of aerosol water and is generally considered a major loss process. However, studies quantifying the hydrolysis rate of particulate organic nitrates are currently scarce, in part due to the difficulty of isolating the effect of hydrolysis from other confounding processes, such as potential RH-dependent loss of organic nitrate vapors to Teflon chamber walls. Here, our study aims at quantifying the hydrolysis rate of particulate organic nitrates from α-pinene and β-pinene under two oxidation conditions: photooxidation in the presence of NO_x (i.e. daytime) and NO_3 oxidation (i.e. nighttime), taking into account the difference in organic nitrate vapor wall loss rate at different RH. Experiments are conducted in the Georgia Tech Environmental Chamber (GTEC) facility. A large suit of oxidized, speciated gaseous and particulate organic nitrates are measured by Filter Inlet for Gases and AEROsols coupled to High-Resolution Time-of-Flight Chemical Ionization Mass Spectrometer (FIGAERO-HR-ToF-CIMS). The total gaseous and particulate organic nitrates are monitored by Thermal-Dissociation Cavity Attenuated Phase Shift Spectrometer (TD-CAPS), and the total particulate organic nitrate concentration is estimated by High-Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS). For the photooxidation win the presence of NO, there was a clear trend in the evolution of speciated particulate organic nitrates that $C_{10}H_{17}NO_x$ (x = 5-8) peaked first suggesting the first generation products, followed by the peaks of $C_{10}H_{15}NO_x$ and $C_{10}H_{13}NO_x$ indicating further OH aging to produce compounds with lower H:C and higher O:C ratios. This process is expected to take place by the abstraction of H, reaction with NO to create an alkoxy radical, which then forms a carbonyl via decomposition. However, regardless of the molecular formula, all speciated C_{10} particulate organic nitrates, when normalized humid to dry experiments, follow a similar decreasing trend that is identical to the bulk behavior observed in HR-ToF-AMS. This could indicate that the first oxidation step is more important than later steps in determining the susceptibility of particulate organic nitrates. Additionally, we experimentally determine the wall loss rate of organic nitrate vapors in our chamber facility under dry and humid conditions. Results from applying the experimental values in the aerosol kinetic model will be presented and the impact of organic nitrate vapor wall loss on the quantification of hydrolysis rate will be discussed.

1AC.7

Impact of NOx on Secondary Organic Aerosol (SOA) Formation from α-pinene and β-pinene Photo-Oxidation: The Role of Organic Nitrates. Iida Pullinen, SEBASTIAN H. SCHMITT, Mehrnaz Sarrafzadeh, Sungah Kang, Patrick Schlag, Stefanie Andres, Einhard Kleist, Thomas F. Mentel, Franz Rohrer, Monika Springer, Ralf Tillmann, Jürgen Wildt, Cheng Wu, Defeng Zhao, Andreas Wahner, Astrid Kiendler-Scharr, *Forschungszentrum Jülich*

Impacts of nitrogen oxides (NO_X) on the formation of gas phase organic nitrates (ON) and subsequent Secondary Organic Aerosol (SOA) mass formation were investigated in a constantly stirred tank reactor. This work focuses on understanding the mechanisms that results in suppression of SOA mass formation from α-pinene and β-pinene photo-oxidation in the presence of high NO_x concentrations. Here we will demonstrate that ON formation alone cannot explain this NOx impact.

Effective uptake coefficients (γ_{eff}) were measured for Highly Oxidized Multifunctional molecules (HOM), which has been found to be dependent on the number of oxygen atoms in the respective HOM. It has been observed that HOM with more than 6 O-atoms were efficiently lost on particles while the loss of HOM containing more than 8 O-atoms, was collision limited. There was no systematic difference between γeff measured for HOM-organic nitrates (HOM-ON) and other monomer termination products such as ketones, alcohols or hydroperoxides. This similarity was attributed to the multifunctional character of the HOM. Since both number and character of most functional groups in monomer HOM with the same precursor HOM-peroxy radical are identical, the vapor pressures of such HOM are within the same range. Thus the suppressing effect of NO_X on SOA formation cannot be explained by the production of HOM-ON replacing other monomer termination products of peroxy radical – peroxy radical reactions.

Comparison of the fraction of organic bound nitrate ($OrgNO_3$) stored in potential particle precursors to the fraction of $_{OrgNO3}$ in the particles, revealed a substantial lack of $OrgNO_3$ in the particle phase. This suggests a strong sink for organic nitrates in the particles. This sink could be due to hydrolysis which forms either HNO_3 or an organic rest. Evaporation of HNO_3 formed by hydrolysis of HOM-ON could possibly explain the missing OrgNO3 in the particle phase but not the 20-30 % lower SOA yields in presence of high NO_X concentrations.

1AC.8

The Impact of Aerosol Uptake of Organic Nitrates on Simulated Surface Ozone in CAM-Chem. REBECCA SCHWANTES, Louisa Emmons, Simone Tilmes, John Orlando, Geoffrey Tyndall, *National Center for Atmospheric Research*

Many regions in the United States have poor air quality because of high levels of ozone. Ozone is intrinsically hard to simulate in global and regional models because the amount of ozone present is controlled by large non-linear sources and sinks. Recently, the chemical mechanism for isoprene and monoterpene oxidation has been updated in CAM-Chem (Community Atmosphere Model with chemistry), which is a component of the Community Earth System Model (CESM). Assumptions made in the model about the aerosol uptake of organic nitrates derived from isoprene and monoterpene oxidation significantly impact ozone formation. This study will comprehensively examine assumptions made in the aerosol uptake of various organic nitrates in the model including those derived from isoprene and monoterpene oxidation. Additionally, if necessary, the aerosol uptake of other relevant chemical compounds will also be updated. The updated model results will be evaluated against data collected during the Studies of Emissions Atmospheric Composition, Clouds and Climate Coupling by Regional Surveys (SEAC4RS) field campaign. The impact of uncertainties in the organic nitrate aerosol uptake on simulated surface ozone will be presented to motivate and direct future research in understanding this complex process. Results suggest that a more explicit treatment of secondary organic aerosol formation in models used to understand air quality is not only necessary for describing aerosol correctly, but also necessary for accurately simulating ozone.

1AM.1

Insights into Isoprene-Epoxydiol SOA Chemistry in Cloud Droplets using WRF-Chem and HI-SCALE Field Observations.

MANISHKUMAR SHRIVASTAVA, Alla Zelenyuk, David Bell, Jerome Fast, Joel A. Thornton, Dan Imre, Kaitlyn J. Suski, Larry Berg, John Shilling, Jiumeng Liu, Fan Mei, Jason Tomlinson, Jian Wang, *Pacific Northwest National Laboratory*

Multiphase chemistry of isoprene epoxydiols (IEPOX) is an important pathway resulting in the formation of IEPOX-SOA. A number of studies report substantial IEPOX-SOA formation on wet sulfate aerosols, at many locations globally. However, IEPOX-SOA formation in clouds has not been reported previously. Measurements during recent HI-SCALE field Campaign provide direct evidence for IEPOX-SOA formation in cloud droplets.

To simulate this process, we implemented IEPOX-SOA chemistry module in WRF-Chem and applied this chemistry to both wet interstitial aerosols and cloud droplets based on the simpleGamma multiphase kinetic model [Woo and McNeill, 2015]. WRF-Chem simulations are conducted at high spatial resolution (1.3 km grids). We analyze model results over the southeast part of our modeling domain that abounds in biogenic isoprene emissions. Simulations show that at cloud level, average concentration of gas-phase IEPOX that dissolves in cloud droplets (40 ng m-3) is an order of magnitude higher compared to dissolved IEPOX in wet aerosols (3 ng m-3) due to significantly larger cloud droplet water content as compared to interstitial aerosols. Further reaction of dissolved IEPOX results in the formation of IEPOX-SOA. However, since reaction kinetics are significantly slower in more dilute cloud droplets as compared to interstitial aerosols, previous studies often neglect the role of cloud chemistry in IEPOX-SOA formation. In contrast, our simulations indicate that formation of IEPOX-SOA in clouds is 3 times greater than IEPOX-SOA in interstitial aerosols. Simulations indicate that conversion of dissolved IEPOX to IEPOX-SOA is indeed slower in cloud droplets compared to interstitial aerosols (10% in cloud droplets, 50% in interstitial aerosols). However, this slow conversion is compensated by large amounts of dissolved IEPOX available in cloud droplets compared to interstitial aerosols. Model results are in good agreement with measurements by the single particle mass spectrometer, miniSPLAT, which indicates preferential formation of IEPOX-SOA in cloud droplets. Simulations also indicate that when cloud droplets evaporate, cloud-phase IEPOX-SOA becomes part of interstitial aerosols, increasing interstitial IEPOX-SOA by a factor of 2. Future work will investigate factors affecting observed regional variations in IEPOX-SOA such as variations in aerosol and cloud properties, biogenic emissions, and their aging in the atmosphere.

Long-term Trends in Simulated Ultrafine Particle Concentrations in California. Xin Yu, Anikender Kumar, Melissa Venecek, Abhishek Dhiman, MICHAEL KLEEMAN, *University of California, Davis*

Ambient ultrafine particles have toxic properties due to their high ratio of surface area to volume that promotes biochemical reactions with adsorbed components such as metals. Ultrafine particles can also cross cell membranes once inside the body allowing them to reach a wide range of organs. Recent epidemiological studies have shown that ultrafine particles are associated with premature death in California, but comprehensive exposure data for ultrafine particles are missing which makes it difficult to estimate the total public health impact.

Here we predict exposure fields for ultrafine particles over California for the period 1996 through 2016 with 4km spatial resolution and daily time resolution. Long term trends in ultrafine particle concentrations are compared to field measurements that span this study period. Source apportionment predictions based on the regional model calculations are compared to receptor-oriented source apportionment results using the chemical mass balance (CMB) model and the positive matrix factorization (PMF) model. The effects of various control programs for mobile sources and biomass combustion are investigated in both the modeled concentrations and the measured concentrations of ultrafine particles over the decades. Implications for exposure and public health are discussed.

1AM.3

Physical and Model-based Characterization of NPF Events and Sensitivity of CN and CCN to Changes in Anthropogenic Emissions in the Midwestern United States. Can Dong, Robert Bullard, Ashish Singh, Scott N. Spak, Hitoshi Matsui, CHARLES STANIER, *University of Iowa*

New particle formation (NPF) is a frequently observed phenomenon worldwide. Ten months (July 2013 to June 2014) of continuous measurements of particle number size distribution were performed at a rural Midwestern United States location (Bondville, Illinois), spanning sizes from 3 nm to 2.5 microns. Bondville is representative of Midwestern United States and other perturbed continental locations with moderate sulfur dioxide (SO2) and fine particulate matter (PM2.5) concentrations (i.e. SO2 of 0.5-3 ppb, PM2.5 of 5-15 µg/m3) at background sites.

New particle formation behavior at the site is similar to other mid-latitude sites, with NPF in 2013-2014 occurring on 44.1% of classifiable days, highest NPF frequency in spring and fall, followed by summer and lowest in winter. Observed growth rates for measured nucleation mode particles (3-25 nm) were highest (8.97 nm/h) in summer and lowest (1.45 nm/h) in winter.

SO2 and sulfate concentrations are dropping in the region, and the fractional importance of secondary organic aerosol is increasing (SOA). For example, at Bondville, SO2 fell from 2.1 to 0.8 ppb from 2005 to 2013, a 62% decrease. As a test of the nucleation explicit version of WRF-Chem, which simulates nucleation using a 20-bin sectional model down to 1 nm, each season was simulated using 2005 NEI (higher SO2 emissions), 2011 NEI (lower SO2 emissions), and sensitivity tests were done with inclusion and exclusion of growth by SOA.

NPF events were captured well by the NPF-explicit WRF-Chem model in April and November without considering secondary organic aerosol (SOA) formation. The two anthropogenic emission inventories, i.e. 2005 NEI and 2011 NEI, were used to study sensitivities of CN (condensation nuclei) and CCN (cloud condensation nuclei) to emissions in the Midwest. Modeling results show that SO2 emission reduction is the primary cause for CN number concentration change. Switching SO2 emissions from 2005 NEI to 2011 NEI led to significant decrease of CN10 (particles with sizes larger than 10 nm) number concentrations, especially in April, September and November (over 20% decrease). On average, model simulated SO2 concentrations by using 2011 NEI were approximately half of the values simulated by using 2005 NEI (2.17 ppb vs 4.32 ppb). Changes of primary aerosol and NH3 emissions also play a role, but the influence is not as significant as that of SO2. Simulated changes of CCN at lower water supersaturations (0.2%) were complicated due to interactions between meteorology and chemistry. At higher water supersaturations (1%), CCN changes were consistent with that of CN10.

Comparison to independent measurements of ultrafine particle number with height (by numerous light aircraft flights) showed that the model's aerosol number predictions do not decrease fast enough with height, an indication of the model having too much vertical mixing, insufficient particle removal, or too strong of a free tropospheric nucleation source.

During the February and September simulation periods, bursts of new particles were reproduced but the subsequent growth was not. The sensitivity of model performance on meteorology and SOA is discussed. Finally, simulations with very low SO2 emissions are performed to show the impacts on air quality, CCN, and the number size distribution under future such scenarios.

Mutual Information Method for Understanding Key Variables in Atmospheric New-Particle Formation. MARTHA ARBAYANI ZAIDAN, Ville Haapasilta, Rishi Relan, Pauli Paasonen, Veli-Matti Kerminen, Heikki Junninen, Markku Kulmala, Adam S. Foster, *Helsinki University*

New-particle formation (NPF) is an important phenomenon occurring in the atmosphere. This process is very non-linear and complex, involving atmospheric chemistry of precursors and clustering physics as well as subsequent growth before NPF can be observed. Thanks to ongoing efforts, tremendous amounts of atmospheric data is now available, generated from simulation models and laboratory experiments as well as continuous measurements directly from the atmosphere. This fact makes data analysis by human brains as well as via traditional statistical methods more challenging, but on the other hand enables to usage of modern data science techniques. In this work, we investigate the use of mutual information method to understand the relationship between observed NPF events (measured at Hyytiälä, Finland) and a wide variety of simultaneously monitored ambient variables: trace gas, aerosol particle concentrations, meteorology, radiation and a few derived quantities. The investigation aims to identify key factors contributing to the NPF. The applied mutual information method finds that the formation events correlate with water content, sulfuric acid concentration, ultraviolet radiation, condensation sink and temperature. Previously, these quantities have been known to be key factors in the phenomenon via dedicated field studies and laboratory as well as theoretical research. The novelty of this work is in demonstrating that the same results can be obtained by the proposed data analysis method which operates without supervision and physical insight. This suggests that the method is appropriate to be implemented widely in the field of atmospheric sciences to discover other interesting phenomena and its relevant variables.

Efficient Wet Removal of Soluble Species through Deep Convection Simulated in Chemistry-Climate Models. PENGFEI YU, Karl D. Froyd, Owen Toon, Charles Bardeen, Shang Liu, Ru-Shan Gao, Christina Williamson, Agnieszka Kupc, Charles Brock, Joshua P. Schwarz, Michael Mills, Simone Tilmes, Karen Rosenlof, Daniel Murphy, *NOAA ESRL and CIRES*

Convective transport determines the vertical transport efficiencies of aerosols and other trace gases in the chemistry-climate models. Parameterizations of convective transport in numerical models especially in chemistry-climate models are of large uncertainties. In the study we shows that the default parameterization scheme in NCAR/DOE Community Earth System model shows a large discrepancy of a factor of 10-1000 on aerosol mass budget against the observations. A modified transport scheme considering activation of aerosol above cloud-base and aerosol-cloud interactions in the sub-grid scale provides much improved agreements. We use various measurements on aerosol mass concentration from a number of field campaigns including Atom1, HIPPO1-5, and balloon-borne measurements over Kunming, China to validate and quantify the convective transport efficiency in chemistry-climate models.

New Method to Modeling Heterogeneous Reaction of SO2 during Haze in China. SHUPING ZHANG, Jia Xing, Biwu Chu, Hong He, Golam Sarwar, Kebin He, Yan Zhao, *RCEES, CAS, China*

In recent years, haze in China has been a hot topic in the study of aerosol chemistry and modeling, while the simulation of heterogeneous sulfate formation is still a big challenge. Literature suggests that different studies used different parameterized methods and heterogeneous oxidation rate of SO_2, which limits application of the haze modeling. To address that issue, this study developed a parameterization using experimental results that are more direct and approximate to the haze generation conditions in China, based on the linear interpolation of the literature uptake coefficient. After summarizing the relevant coefficient of uptake, a series of experiments are conducted to investigate the heterogeneous uptake of SO_2 under the atmospheric reaction condition of different relative humidity with the coexistence of NH_3 and NO_2 on the real dust surface. The uptake coefficient under different relative humidity in CMAQ model is parameterized based on the experimental results. We establish a parametric approach to model the heterogeneous oxidation of SO_2 to sulfate under the coexistence of NH_3 using the more direct experimental data. This parameterization method can improve the model performance in the simulation of Beijing sulfate in winter 2014 by 9.18%. The heterogeneous oxidation of SO_2 in the presence of NH3 can contribute to 17% of the sulfate concentration during periods of heavy pollution.

1AM.7

Sparse-particle Methods for Simulation of Atmospheric Aerosol. LAURA FIERCE, Robert McGraw, *Brookhaven National Laboratory*

Aerosol effects on clouds and radiation have remained a large source of uncertainty in quantifying anthropogenic changes to the Earth's energy balance, despite increases in model complexity. Climate-relevant aerosol properties depend on characteristics of individual particles, but particle-level characteristics are not easily represented in global models. Instead, global and regional aerosol schemes approximate the representation of particle size and composition, leading to errors in prediction of direct and indirect aerosol effects that have not been well quantified. At the other extreme, the particle-resolved PartMC-MOSAIC simulates the evolution of the full particle mixing state using a Monte Carlo approach but is computationally too expensive for large-scale simulation. Here a new framework is introduced for simulation complex aerosol distributions, based on the quadrature method of moments. Key features of aerosol populations are captured using quadrature approximations of multivariate moments. Each quadrature consists of a collection of abscissas, or representative particles, and associated weights. Distributions with respect to key aerosol quantities, such as the critical supersaturation for CCN activation or optical cross sections, can be approximately reconstructed using constrained maximum entropy distributions. Unlike other reduced aerosol schemes, such as modal and sectional models, the sparse-particle approach is not constrained to pre-determined size bins or assumed distribution shapes. CCN activity and optical properties from the sparse aerosol simulations are benchmarked against the particle-resolved model PartMC-MOSAIC. This study is a first step toward a new aerosol simulation scheme for large-scale simulations that will track multivariate aerosol distributions with sufficient computational efficiency for large-scale simulations.

1AM.8

Constraining Aerosol Processes with a Stability-Based Inverse Model. DANA MCGUFFIN, Peter Adams, Erik B. Ydstie, *Carnegie Mellon University*

The general dynamic equation predicts the evolution of aerosol size distributions with terms that represent emission, nucleation, condensation, coagulation, and deposition of particles. This work aims to constrain key uncertain terms in the general dynamic equation using measured size distributions. Coagulation of particles is calculated based on their Brownian motion and the loss rate includes deposition to the ground and advection. However emission, nucleation, and condensation of volatile organic compounds (VOCs) are highly uncertain. Primary aerosol emissions are difficult to monitor and calculate due to the variability in emission fluxes and intensity levels within a sector. The nucleation of particles from molecular clusters of compounds possibly including sulfuric acid, water, amines, and organic compounds is still an active area of research. Secondary organic aerosols (SOA) are generated as VOCs condense to the particle phase or on pre-existing aerosol, but there are large uncertainties in the identity of VOC precursors and the condensation mechanism as well as in the SOA budget.

The goal of this work is to use measured aerosol size distributions to gain knowledge on three uncertain aerosol processes: primary organic aerosol emissions, nucleation rate, and SOA production. Such measurements of aerosol mass and number size distributions implicitly contain a great deal of information about these microphysical processes, and they are available at several ground sites. We integrate size distribution measurements and an aerosol microphysics model using nonlinear process control theory.

Measured size distributions are generally used to validate models through sensitivity analyses in forward models. In these cases, tuning factors or model parameters are systematically adjusted until the model reproduces a measured distribution of aerosols. However, a more robust way to do this is to generate and run an inverse model.

In general, inverse models are used to constrain uncertain processes based on a set of measurements. Inverse models usually minimize a cost function related to the sum of squared error in the set of observations by linearizing the forward model. However, inverse modeling of aerosol microphysics is challenging since it involves nonlinearities that span large spatial and temporal scales. This work develops a new, stability-based inverse modeling technique that is not computationally intensive and rigorously accounts for nonlinear dynamics.

Here, we present the development of the inverse modeling technique and preliminary applications to a box model. We use a zero-dimensional version of the TOMAS microphysical code, which models size-resolved aerosols with the discretized general dynamic equation. We generate synthetic measurements by running TOMAS with a set of “true” rates for primary emissions, nucleation, and SOA production. Then, we start a TOMAS simulation with a set of process rates biased from their “true” value. We will see if the developed inverse modelling technique will estimate the “true” process rates based on the synthetic measurements. The methodology developed here will facilitate future work that estimates primary aerosol emissions, nucleation, and SOA production in a global model based on a measurement network.

1CM.1

Comparison of Different Neutralizing Methods by IPA on Electret Filter Media. MIN TANG, Sheng-Chieh Chen, Drew Thompson, David Y. H. Pui, *University of Minnesota*

It has been broadly demonstrated that electrostatic charges added to polymer fibers by creating electrets will improve particle capture abilities without increasing the pressure drop. Filtration applications require knowledge of the minimum efficiency provided by a filter (worst-case performance). In existing test standards, e.g. EN 779 and ISO 16890, isopropanol (IPA, in liquid or vapor phase) is used to eliminate electrostatic effects from filter media. There is few report about whether IPA liquid and vapor can fully discharge the electret media. Currently, there is a huge controversy in fiber charge characterization techniques for electret media. This study developed a simple and reliable method to determine whether the filter media were fully discharged. The neutralization effect of IPA liquid and vapor discharging was compared. The results showed that IPA vapor treatment showed better neutralization effect than IPA liquid immersion, since IPA liquid treatment can induce undesirable charges on fiber surface. It was found that IPA vapor did not have the ability to discharge electret media. The discharging process was that IPA vapor condensed on the charged surface and remove the static charge. Proper design of IPA vapor chamber to allow vapor condensation on fiber surface is important to efficiently remove charges of electret media.

1CM.2

Filtrationof Liquid Aerosol on Fibrous Filters Modified with Silica Aerogel - Experimental and Modeling Study. JAKUB GAC, Bartosz Nowak, Marta Bojarska, *Warsaw University of Technology*

Removal of liquid droplets from gas flow is one of the most important process in many industrial processes (i.e. gas processing) environmental protection (air cleaning). One of the most efficient method to manage it is a filtration of a fibrous filters. For a last decade some methods of additional improvement filtration efficiency on such filters are investigated.

In our work we propose the modification of filters by covering their fiber with silica aerogels. These aerogels are material characterised by very high porosity, low density and extremely oleofilic properties. In our study they are obtained by means of sol-gel process. Last stage of this process is conducted in the presence of fibrous filter what causes the deposition of aerogel on fibers of this filter.

Our investigations show that such a filter has much greater efficiency than unmodified one. One of the reason us a presence of aerogel structures which act as additive collectors. The other effect is good sorprive properties of aerogel in respect to oil.

The experimental findings are confirmed with results of modeling of oil droplet filtration of single fiber covered by aerogel structure.

Adsorption Characteristics of Sub-10nm Nanoparticles on Porous Materials. ZIYI LI, Yingshu Liu, Chuen-Jinn Tsai, Yi Xing, Pei Lu, Likun Yin, Ralph Yang, *University of Science and Technology Beijing*

Adsorption of tiny nanoparticles with sizes close to gases on porous materials, such as activated carbons and zeolites, has been a long-existed and unrevealed issue in the gas separation field. Several recent studies dealing with PM2.5 using activated carbons (Kim et al., 2016), MOFs-coated filters (Chen et al., 2017), and nanofiber-coated window screens (Khalid et al., 2017) have shown functions of porous structure in trapping particles, and thus the lack of consideration on filter material effects for predicting filtration efficiency at nanometer range based on traditional theory. On the other hand, nanoparticles behaving like gas molecules are able to easily diffuse deep into porous networks, which would influence the utilization of adsorbents in practical gas separation (Kim et al., 2017), and needs theoretical directions for protection.

Herein, we demonstrate this particular phenomenon by conducting the removal efficiency test for sub-10 nanoparticles filtered by mesoporous adsorbents with different morphologies, including CMK-3, CMK-5, KIT-6, and a series of SBA-15 with the primary pore size range of 5.8-17.8 nm, and by FAU zeolites ion-exchanged with different cations such as Li+, Na+, K+, Mg2+, Ca2+ and Sr2+. The results show efficiency curves different from those predicted by Brownian diffusion filtration theory which always get close to 100% below 10nm, and varied in a regular manner with adsorbent properties. The effects of morphologies, pore size distributions and ion exchange properties on nanoparticle capture will be explored in details based on material characterizations, adsorption theories, and molecular simulations.

Keywords: nanoparticles, porous materials, adsorption, removal efficiency test, molecular simulation

Filtration Performance of a Melt Electrospun Filter Material. DAINIUS MARTUZEVICIUS, Dalia Buivydiene, Edvinas Krugly, Darius Ciuzas, Tadas Prasauskas, Linas Kliucininkas, *Kaunas University of Technology, Lithuania*

INTRODUCTION. Air filtration sector continuously seeks of the development of high-durability filters, having high efficiency and low pressure drop. Nanofbrous filters, however, face issues with relatively low quality factor, since high efficiency is counter levered by high pressure drop. Melt electrospinning has emerged as an efficient technique for the formation of polymer nonwowen filtration mats. Such technique may be tuned so that the produced fibres range broadly in diameter, providing optimum efficiency with relatively low pressure drop. The presented study presents the development and testing of such filtration media.

METHODS AND MATERIALS. The prototype fibre printing apparatus was constructed by uniting principles of additive 3D printing and melt electrospinning. The apparatus consisted of movable arm holding electric heater and exchangeable nozzles combined with high voltage source to form a positively charged electrode. A spinning collector drum served as a grounded electrode.

A commercially available polymer having a relatively low viscosity and high melt flow rate (Vestamid™ L 1600, Evonik AG) was spun. During 1 hour of spinning, a mat of the area 150 cm2 with mass, depending on feed rate of polymer ranging from 26 g/m^2 to 122 g/m^2.

The obtained fibre mats were subjected to the air filtration tests. NaCl aerosol was generated using Collison nebulizer (Model CN 24 J, BGI Inc., USA), dried by diffusion dryer packed with silica gel, diluted with dry air and charge equalized using bi-polar neutralizer (3054A, TSI Inc.). 37 mm round sample of mats were tested, measuring upstream and downstream concentrations of particles by ELPI+ (Electrical Low Pressure Impactor, Dekati Ltd., Finland). The pressure drop before and after filtration media was measured by a pressure sensor (Model P300-5-in-D, Pace Scientific Inc., USA). Filtration efficiency (η) and Quality Factor (QF) were calculated based on the particle concentration measurements.

RESULTS. Various distributions of fibre diameters were obtained, with the mean ranging from 2.8 to 8.6 µm. By-layered structure has been achieved, with the top layer slightly more uniform with diameter modes at ≤1 µm and between 2 - 5 µm while bottom layer was a mixture of fibres with diameters ranging from 0.3 to 27.4 µm distributed in bi- or three modal manner.

The quality factor was calculated as a ratio between filtration efficiency and pressure drop with the aim to better compare manufactured filter media to off-shelf filtration materials. The calculated quality factor ranged from 0.206 Pa^{-1} to 0.320 Pa^{-1} for different mats. As a comparison, the tested commercial H13 filter material had a QF of 0.029 Pa^{-1}. Such higher performance of the melt-spun materials may be attributed to an optimum morphology as well as lower base weight.

Further challenges to the optimization of the setup include increasing through output of the spinning. A polymer material having decreased melting temperature and increased melt flowrate as well as bearing high mechanical stability would also increase the opportunity for the expansion for this technique in air filtration sector.

Filtration Performances Study of Porous Media Composing Protective Clothing Against Solid Aerosols. LOÏC WINGERT, Ludovic Tuduri, Yves Cloutier, Stéphane Hallé, Ali Bahloul, Dominique Tessier, Jean-Luc Giraudel, Patricia Dolez, Pearl Yip, *IRSST/ETS*

Aerosols found in workplaces depend on workers activity or industrial processes (metallization, asbestos removal or waste treatment …). The particles emitted by these activities can be very different from each other. Metallization fumes are made, for example, of ultrafine particles (UFPs) of metal oxide whereas those found in electronic waste industry are often micron-sized and composed of heavy metals. Some micron-sized particles, such as the beryllium, represent a proven health hazard by skin contact leading to airborne dermatitis. Only a few studies are available on skin damages related to UFPs. Nonetheless, they already highlight a risk of cytotoxicity and migration to ganglia and organs. Despite these potential danger to the skin, no cutaneous threshold limit values (TLV) exists for solid aerosols. This absence of TLV together with the known health hazards of some common solid aerosols and the lack of knowledge on the UFPs has led, as a precaution, to the use of chemical protective garments (CPG). According to the ISO 16602 standards, CPG against solid aerosols are classified as type-5 and must meet a minimal performance level defined by the ISO 13982-1 and ISO 13982-2 standards. Since there is no hierarchy between all the certified type-5 CPG, significant differences between their protective efficiency could exist and this might lead to an over or under-protection of the workers.

Thus, it was decided to study the filtration performances of the fabrics/materials composing a wide range (20) of type-5 CPG among those available in North America. Amongst, the CPG selected for this study nine were made of microporous fabrics (MP), ten of multilayered nonwoven fibrous media (SMS, SMMS/SMMMS)* and one of a fabric produced by flash spinning process (FS). In order to expose these materials to a wide range of particle sizes (ultrafine to micron-sized), such as those that could be found in workplaces, a 20 nm to 2000 nm diameter sodium chloride aerosols was produced by nebulization in a wind tunnel. Furthermore, penetration experiments were performed at three different low air velocities (0.05, 0.15, 0.3 cm/s) in order to be as close as possible to velocities encountered in real situations. To ensure the robustness of the results, each experiment was triplicated. The collection efficiency was computed from the particle size distributions measured upstream and downstream of the tested samples by using a SMPS (3936, TSI) / APS (UVAPS 3314, TSI) tandem. In addition to the penetration or collection efficiency, the air permeability of the different CPG was also measured.

These permeability measurements allowed, for the first time, to rank the materials of the most commonly used type-5 CPG in North America into distinct clusters corresponding to the different kinds of materials (MP, SMS, SMMS/SMMMS, FS), regardless of the manufacturing company. Separated material groups were also observed from the collection efficiency measurements, but with some differences. In particular, the SMS materials showed very different collection efficiency from each other, i.e., between 45% and 99%. These differences were explained by microscopic analysis and by the physical characterizations of the media. Given that air and vapour permeability are factors correlating with thermal comfort, all these results, constitute a first important step for the choice of the most suited CPG against solid aerosols for a given workplace.

Control of Cooking Oil Fume Emission by the Combination of an Ionic Air Purifier and Bed Filter Packed with Recycled Wastes. Kuo-Pin Yu, Xuan-En Yang, Yen-Chi Chen, CHUN-HSUAN BAI, *National Yang-Ming University*

This study investigated the removal of cooking oil fume by using bed filter packed with 100 gram of recycled waste materials, including tea leaf (TL), wood dusts (WD), rice hulls (RH) and coffee grounds (CG).The removal efficiency of bed filter for particles larger than 1 µm was higher than 95%. For the removal of submicron particles, the ranking of the packing of the performance of the testing materials was in the order of RH, WD, CG, and TL. Ionic air purifier can enhance the removal efficiency of bed filter on submicron particles, particularly the CG filter. The removal efficiency of volatile organic compounds by bed filter ranged from 18.22 to 30.17%.

1CM.7

Combined Effect of Aerosol Concentration and Humidity on Laboratory Filter Loading Experiments. QISHENG OU, David Y. H. Pui, *University of Minnesota*

Current air filter test standards and laboratory evaluations employ artificial testing aerosols to assess filter performance. Solid particle size distribution was found to significantly affect filter lifetime, so it is often reported specifically in reports and literature, together with other operational parameters, such as filtration velocity, temperature, and pressure if applicable. Test aerosol concentration and humidity are another two factors that may affect filter performance, however, in a long time, enough attention has hardly been paid. In order to achieve reasonable test durations, laboratory filter loading tests are often accelerated with aerosol concentration much higher than real application in the field, which is particularly true for filters facing ambient air, such as those in air intake, HVAC, or air cleaning applications. Although suspicious, it is often accepted that the orders of magnitude difference in concentration (μg/m^3 in field vs. mg/m^3 or even g/m^3 in laboratory) has negligible impact on filter lifetime. Relative humidity (RH) was found to affect filter holding capacity, especially for those loaded by hygroscopic aerosols. Unfortunately, humidity is often not controlled, monitored, or reported in literature even when hygroscopic salt particles present.

In this study, the effect of aerosol concentration and test humidity is experimentally evaluated by loading air intake filter media with hygroscopic salts at varied concentrations and RHs. Besides potassium chloride as a typical laboratory salt, ammonium sulfate and ammonium nitrite, which are more abundant in atmosphere, are employed to better represent ambient particle speciation. At same concentration level, filter holding capacity increases with RH increasing as long as particles kept “dry” below their deliquescent RH, which is mainly attributed to the morphological change on particle dendrite and cake due to moisture-salt interaction by capillary condensation. This effect is more pronounced at lower concentration as more time is allowed to develop towards a steady state, which is very difficult to reach from observation in this study. The rate of morphological change competes with the loading rate, so that the observed pressure drop evolution during a loading test represents a combined effect of aerosol concentration and testing RH. At high RHs, where rapid interaction between salt and moisture occurs, the effect of concentration becomes significant. Particles with different hydration-dehydration cycles response differently to RH and concentration level. Detail discussion will be given in the presentation.

1CM.8

Effect of Pore Structures on Filtration Performance of Diesel Particulate Filters Based on 3-D Simulation.

CHENG CHANG, Qisheng Ou, Yun Liang, David Y. H. Pui, *University of Minnesota*

Diesel particulate filters (DPFs) are widely used on diesel engines after-treatment system to mitigate the particulate matter emission. It was found experimentally that pore structures of DPF substrate greatly affected its pressure drop and filtration efficiency. Efforts have been made to correlate substrate pore structure and its filtration performance employing numerical simulations. A large number of numerical methods have been developed to simulate the filtration process, however, mainly based on modeled pore structures which could not sufficiently present the realistic structure of filter substrates. 3-D simulation of DPF performances is rarely reported. In this study, the pore size distribution and porosity of substrates were measured by both mercury porosimetry and X-ray micro-computed tomography (μ-CT). The filtration performance of DPFs was further predicted based on the 3-D micro-structure from μ-CT scans, which was compared with the experimental characterizations. Substrates with different pore structures were then established, from which the effect of porosity and pore size distribution on the particulate deposition in the substrates and filtration performance was further discussed. The results showed that there was a good agreement between the predicted values and experimental results. The most penetrating particle size varied with pore size distribution. In addition, the operational conditions, such as testing temperature and velocity, were found to significantly influence the filtration efficiency.

Optical and Electronic Properties of Flame-Synthesized Carbon Nanoparticles. CHIARA SAGGESE, Ajay V. Singh, Lucy Kaye, Hai Wang, *Stanford University*

Combustion-generated aerosol (soot) or smoke is a notorious air pollutant with hazardous effects on human health and wide-ranging impacts on regional and global climate. Nevertheless, it was only recognized very recently that nascent flame soot particles, i.e., those intercepted during early stages of formation, exhibit fascinating optical and electronic properties, which can be exploited for potential applications in energy conversion and medical diagnostic [1, 2].

In this work, carbon nanoparticles (CNPs) with sizes around 10 nm are synthesized using a series of laminar premixed burner-stabilized stagnation flames [3] and CNPs properties are characterized through UV-visible absorption spectroscopy and fluorescence spectroscopy.

CNPs are collected thermophoretically onto quartz slides at various distances from the burner surface. UV-visible absorption spectra of the particle samples are collected and analyzed in terms of Tauc optical bandgap thus allowing a quantification of the apparent optical bandgap for as-synthesized particles. The results demonstrate the dependency of the optical bandgap on particle size. Fluorescence is observed in the wavelength range of 400-650 nm from particles suspended in organic solvents. Analysis of fluorescence excitation-dependency is carried out and the influence of the solvent is investigated. Implications of these findings will be discussed.

Graphene Nanosheets Produced via Controlled Detonation. Functionalities with Oxygen/Precursor Ratio. ARJUN NEPAL, Justin Wright, Stefan Bossmann, Christopher Sorensen, *Kansas State University*

Systematic studies of the controlled detonation method for the production of nanoscale graphene to determine the role of oxygen content in pre-detonated oxygen/precursor mixtures are presented. Various ratios of hydrocarbon (acetylene and ethylene) and oxygen are used. The resulting graphene is characterized with BET surface area and porosity, Raman and FTIR spectroscopy, TEM and etc. The specific surface area increases with oxygen content, consistent with Raman measurements that indicate less layering. Spectroscopic measurements of the ca. 10 msec detonation flash indicate black body temperatures are also affected by the oxygen/precursor ratio and overlaying emission lines hint at the mechanisms for the graphene production.

1DU.3

Particle Formation in Combustion Environments: Importance of Charge Distributions on Evolution of Aerosol Size Distributions. YANG WANG, Girish Sharma, Michel Attoui, Pratim Biswas, *Washington University in St Louis*

Combustion systems result in the production of particles both inadvertently and intentionally. The evolution of the size distribution is an important factor in both cases - either for the control of emissions of particles or for the production of novel materials. Charging in flames significantly affects the properties of the particles produced because of its influence in almost all stages of particle formation. In situ measurements with enhanced particle detectors in a premixed flat flame showed that up to 95% of the flame-generated sub-3 nm particles were charged at a sampling height of 5 mm above the burner, indicating the existence of a strong ionization process. The flame-generated ions play an important role during particle inception, as shown by the attachment of ionic species on the particles. Hence, the charging process and the resultant aerosol charge distributions should be considered in aerosol dynamics modeling to accurately predict the behavior of the high-temperature aerosol system. First, this is contrary to reports that most particles below a certain size (~ 5 nm) are not charged. Second, existing models do not consider particle charging, which may lead to a bias in the calculated size distributions.

In this study, Fuchs' charging theory was coupled with aerosol dynamics models to investigate the influence of charging on the evolution of aerosol size distributions in combustion environments. A monodisperse particle growth model and a model using the method of moments were developed and compared in simulating the simultaneous particle charging and coagulation at high temperatures. In order to quantify the charging characteristics of nanoparticles, a high-resolution DMA was used to measure the mobilities of ions generated from a premixed flat flame operated at various conditions. The effect of temperature on ion-particle and particle-particle combination coefficients was further examined. The proposed models showed that the influence of charging on particle growth dynamics was more prominent when the ion concentration was comparable to or higher than the particle concentrations, a condition which may be encountered in flame synthesis and solid fuel-burning. Simulated results also showed that unipolar ion environments strongly suppressed the coagulation of particles. In the end, a simplified analysis of the relative importance of particle charging and coagulation was proposed by comparing the characteristic time scales of these two mechanisms.

Crystal Structure and Surface Composition of Coalescing Ag-Au Nano-Alloys by Molecular Dynamics Simulations.

EIRINI GOUDELI, Sotiris E. Pratsinis, *University of Minnesota*

Bimetallic nanoparticles exhibit catalytic, optical, electronic and magnetic synergy between their constituents. Typically, that synergy is traced to the structure and surface characteristics of such particles. Core-monolayer shell bimetallics exhibit often unique properties that are not an interpolation between those of their parent metals. This behavior is attributed to the lattice mismatch (strain effect) and charge transfer between layers (ligand effect) resulting in different electronic properties. Furthermore, the addition of an ad-metal may alter also the reactant adsorption geometries (ensemble effect) and the degree of ad-metal coverage and its diffusion into the bulk alter the adsorbate binding energies. Yet, there is only limited understanding of the structure and mixing of the two parent metals. Furthermore, understanding metal-adsorbate interactions is a key issue to controlling and improving the functionality of bimetallic nanoparticles in energy applications. Adsorption, however, depends on nanoparticle morphology.

Here, the effect of temperature and initial particle morphology on the sintering rate and crystalline structure is elucidated during sintering of such silver-gold nanoparticles by Molecular Dynamics (MD) simulations. The MD method is validated by the attainment of the melting temperature of pure Ag (Buesser and Pratsinis, 2015), Au (Goudeli and Pratsinis, 2016) and Ag-Au bimetallic nanoparticles as function of their size. The sintering rate of particle pairs with different initial morphology (Ag-Au alloys, segregated or Ag@Au and Au@Ag core-shell nanoparticles) is determined by tracking the evolution of the total surface area and the changes in surface composition of the formed nanoparticle are elucidated during coalescence at T = 500 – 1000 K. The XRD pattern of Ag-Au nanoparticle composites is calculated and compared with experiments (Sotiriou et al., 2014) while their crystallite size is obtained by fitting these MD-obtained XRD patterns (Goudeli and Pratsinis, 2017).

Pure Ag and segregated Ag-Au nanoparticles have larger XRD size than pure Au or alloyed Ag-Au ones. This can provide indication of the detailed structure of flame-made nanoparticles at the atomistic level as experimental measurements of Ag-Au particle size revealed smaller XRD diameter than pure Au or Ag particles (Sotiriou et al., 2014). Furthermore, sintering of Ag@Au core-shell nanoparticles leads to slight reduction (less than 10%) in Ag surface composition, in contrast to Au@Ag ones that increase their Ag surface composition more than 20%.

Synthesis of $Li_{1.2}Mn_{0.54}Ni_{0.13}Co_{0.13}O_2$ via Low Temperature Flame Spray Pyrolysis. JOSE MADERO, Kuan-Yu Shen, Jeremy Wojtak, Tianxiang Li, Richard Axelbaum, *Washington University in St. Louis*

Lithium, manganese-rich layered cathode material (LMR-NMC) has been studied intensively in the past decades and is one of the most attractive cathode materials under research. Its ability to reach discharge capacity above 200 $mAhg^{-1}$ and low cobalt content make it a promising candidate for cathode material of electric vehicles. Flame spray pyrolysis has been utilized to synthesize LMR-NMC, however, the material is sensitive to the flame conditions as high temperature may lead to additional phase formation. Herein, a low temperature flame spray pyrolysis (FSP) is proposed for the synthesis of $Li_{1.2}Mn_{0.54}Ni_{0.13}Co_{0.13}O_2$. High water content ethanol was used as a fuel and a swirl-stabilized burner was used to achieve the low reactor temperature which is unlikely to be attained via traditional FSP. The effects of reactor temperature, which is controlled via altering ethanol concentration, on the physical properties and the electrochemical performances of the synthesized materials were characterized. The results indicated that as the flame temperature increased, more distinct Li_2MnO_3 phase (C2/m) was grown and larger primary particles were formed. $Li_{1.2}Mn_{0.54}Ni_{0.13}Co_{0.13}O_2$ synthesized with 25 wt % ethanol showed the best results and delivered a discharge capacity of 203 $mAhg^{-1}$ after 100 cycles under C/3. It also achieved good rate capability showing 201 mAhg -1 and 169 mAhg -1 under C/2 and C/1. These results are comparable to the ones demonstrated by $Li_{1.2}Mn_{0.54}Ni_{0.13}Co_{0.13}O_2$ produced via furnace spray pyrolysis and the state-of- the-art co-precipitation.

1DU.6

Effects of Droplet Diameter and Flame Temperature on Nanoparticle Formation Mechanisms in Liquid Aerosol-Fed Non-Premixed Gas Flames. CHRISTOPHER ABRAM, Maksim Mezhericher, Howard A Stone, Yiguang Ju, *Princeton University*

The formation routes of metal oxide nanoparticles are experimentally investigated in self-sustaining gaseous flames fed by aqueous metal-nitrate solution aerosol droplets. To understand the influence of the precursor droplet diameter on the product particle size and morphology, two different atomisation methods are compared: (1) a novel bubble/gas jet atomisation technique, which generates droplets in the sub-micron range with a number mean diameter of ~200 nm; and (2) conventional ultrasonic atomisation producing droplets with a corresponding diameter of ~3.5 µm. Solution droplets consisting of yttrium and europium nitrate salts dissolved in water are delivered to non-premixed CH_4/N_2-O_2 flames to synthesise Eu-doped Y_2O_3 phosphor particles. The product particles are characterised using SEM, TEM, BET gas adsorption and luminescence spectroscopy. Flame temperatures are measured using planar laser Rayleigh scattering.

Depending on the synthesis temperature, the results show that product particles are formed via two different mechanisms: droplet-to-particle and gas-to-particle. At low flame temperatures (1150 K), sub-micron droplets produce cubic-phase luminescent Y_2O_3:Eu^{3+} nanoparticles via the droplet-to-particle mechanism. The particle size can be controlled from 10 to 100 nm by adjusting the precursor concentration in the 0.01-1 mol/L range. Increasing the flame temperature (1450-2750 K) leads to the formation of nanoparticles with a size 3-5 nm via nucleation and growth in the gas phase. In separate experiments, the aerosol flow was also electrically-preheated to 500 K in order to evaporate the solvent upstream before delivery to the flame. With preheating, under the same high temperature flame conditions, the droplet-to particle formation route dominates instead and very few nanoparticles are formed from the gas phase. This result suggests that even for these non-volatile metal nitrate precursors, vaporisation of the precursor occurs predominantly during the extremely rapid droplet drying when the droplets are exposed to the high temperature gradients in the flame. In such cases, specific surface area measurements of the product powders show that sub-micron droplets form an increased fraction of nanoparticles from the gas phase compared with micron-size droplets, because the greater developed surface area of sub-micron droplets enhances vaporisation of the metal precursor.

Analysis of the relevant timescales indicates that the relative rates of solvent evaporation and bulk solute diffusion are dependent on the droplet size. Electron microscopy confirms that dense particles are formed from sub-micron droplets, even when subjected to a rapid rate of gas temperature increase in the flame ($5x10^4$ K/s). For the same synthesis conditions, micron-size droplets tend to form hollow particles because relatively slow solute diffusion causes precipitation on the droplet surface. In this case either slow preheating of the aerosol upstream of the flame or high downstream peak temperatures near the product melting point (>2700 K) are required to promote dense particle formation.

Pursuing Complex Materials Synthesis by Flame Spray Pyrolysis with Advanced Diagnostics. JOSEPH LIBERA, Stephen Cotty, Theodore Krause, Robert Tranter, Jan Ilavsky, Karena Chapman, Gregory Krumdick, *Argonne National Laboratory*

A Flame Spray Pyrolysis reactor has been commissioned at Argonne National Laboratory for research in materials synthesis. The system features a closed combustion environment with full control of all combustion gases and liquids and includes a high-temperature-residence-time section for post-flame in-situ annealing. The system includes in-situ particle and flame diagnostics: PLIF (planar laser induced fluorescence) and SMPS (scanning mobility particle sizing). The PLIF instrument has been configured to provide FRS (filtered rayleigh scattering) temperature and multiple species imaging (Fe, FeO, OH, SiO, NO, Fe, CH, Li). In addition, combustion solid particles are collected before and after the HTRT section for TEM, and advanced synchrotron diagnostics (PDF-SAXS-WAXS). The system has been deployed for the development of Fe-silica catalyst and doped-LLZO for solid state electrolyte applications. We will present preliminary results of the process development demonstrating the use of the in-situ and ex-situ diagnostics for generating useful particles in flame aerosol combustion.

Two-dimensional Diagnostic of Nanoparticle Formation and Transport in Complex Flames Using Phase-selective Laser-induced Breakdown Spectroscopy. YIYANG ZHANG, Yihua Ren, Shuiqing Li, Stephen Tse, *Tsinghua University*

Recently, a diagnostic technique named phase-selective laser-induced breakdown spectroscopy (PS-LIBS) has been developed, especially aiming at tracing nanoparticle formation and transport in reactive flows. PS-LIBS uses the gap between the breakdown thresholds of gas phase and nanoparticles. By creating nano-sized plasmas around particles without ionization of gas molecules, the technique is able to reveal information from particles while the gas phase is not disturbed. In this study we present our recent work on extending PS-LIBS to two-dimensional imaging and related applications for investigating nanoparticle formation and transport in complex flames. Benefited from the non-spark feature, PS-LIBS can be extended to two-dimensional imaging with bandpass filters, which can not be realized in conventional LIBS measurement. We visualize the quick formation of nanoparticles across the flame sheet, as well as particle transport after the flame. Parametric study shows that the intensity of atomic spectra scales linearly with particle volume fraction. Here we will show two particular examples of two-dimensional PS-LIBS imaging. First, a close-up imaging is used to study particle transport near the stagnation plane of a counter-flow flame. The spatial resolution reaches 10 μm. The measured profile of particle concentration remarkably agrees with the numerical solution of particle transport equation. Another example is single-shot two-dimensional imaging in a turbulent co-flow diffusion flame. The snapshots successfully capture particle concentrate near diffusion flame sheet and diffusion/entrainment to the precursor-free side. The single-shot two-dimensional PS-LIBS imaging can be a powerful tool to study turbulent flame synthesis.

1IA.1

Seasonal Variation in the Composition of Submicron Indoor Aerosols of Outdoor Origin. Anita Avery, Michael Waring, PETER DECARLO, *Drexel University*

Outdoor-originated aerosols play a key role in indoor air quality, especially in indoor spaces without strong sources. Since outdoor aerosol varies both spatially and temporally over short (diurnal) and long (seasonal) time scales. We examined the effect of these changes in aerosol loading and chemical composition on indoor aerosol, by examining both indoor and outdoor aerosols in real time in an urban classroom in winter and summer seasons, using an aerosol mass spectrometer (AMS) and a suite of gas phase instruments. Factor analysis of the organic aerosol components identified 3 factors in common between seasons, including hydrocarbon-like, cooking, and oxidized organic aerosol (HOA, COA, and OOA). We report a sulfate-normalized indoor-outdoor ratio (I/O)i/SO4 to account for seasonal differences and variation in ventilation (HVAC operation) to elucidate emissions and chemically-based loss processes between environments. Outdoor aerosols transported indoors in wintertime experience an increased environmental temperature which can drive off water and volatile components, while in summertime aerosols experience a decrease in temperature upon transport indoors and the reverse can happen. However, the degree to which any effect is observed is dependent on the starting (outdoor) aerosol population and the magnitude of change (in temperature, RH, etc.). The median (I/O)i/SO4 values for nitrate, black carbon (BC), total organics, and HOA were smaller in wintertime when temperature gradients between environments favored losses of volatile components; (I/O)i/SO4 values greater than one indicated indoor sources (or less loss) of HOA, BC, and COA. Calculated aerosol liquid water (ALW), as a function of the environmental conditions (temperature and humidity) and the relative contribution of hygroscopic components, varied significantly by season with higher levels in the summertime providing the possibility of aqueous or otherwise liquid processing. This work describes the linkages between chemically-specific variations in exposure between seasons.

1IA.2

Chemically-Resolved Particle Mass Composition in a Swedish Residence Assessed by a Time-Of-Flight Aerosol Mass Spectrometer.

YULIYA OMELEKHINA, Axel C. Eriksson, Patrik Nilsson, Joakim Pagels, Aneta Wierzbicka, *Lund University, Sweden*

A number of deleterious health effects have been identified from exposure to outdoor airborne particulate matter. Given that in developed countries we spend majority of our time indoors, in private homes about 65 % (Brashe et al., 2005), the understanding of this exposure is important, yet knowledge is sparse. Particle levels indoors are affected by indoor sources, infiltration from outdoors or particle mass forms through reactions of gas-phase precursors emitted both indoors and outdoors (Morawska et al., 2013). The aim of this work was to characterize a chemical composition of particle mass indoors, and to gain a better understanding about major contributors to the observed indoor levels with Aerosol Mass Spectrometer. We aimed to identify mass spectral signatures of specific indoor sources. This is preliminary results of measurements for a 1-month period.

Indoor and outdoor measurements were performed in an occupied residence in Malmö, Sweden. It was a naturally ventilated four-room apartment (292 m^3), located in a three-store concrete building surrounded by a green zone. A Time-of-Flight Aerosol Mass Spectrometer (DeCarlo et al., 2006) was used to measure particle mass loadings and size-resolved mass distributions (50-500 nm) of indoor and outdoor chemical species. An automatic switching valve alternated between indoor and outdoor lines with a time interval of 20 and 10 minutes, respectively. Both sampling lines were mounted at the ground floor level and led to the basement where the aerosols were dried and measured by AMS.

Our results showed higher total average mass concentration indoors (12.9 µg/m^3) compared to outdoors (5.4 µg/m^3) over the entire measuring period. Indoor to outdoor (I/O) ratio for organics was 6.7, for sulphate 0.5, for nitrate 0.3, for ammonium 0.2 and for chloride 0.2. The dominant species indoors was organic matter, accounting for most of the total particle mass (92 %) due to contribution from indoor sources and from outdoor infiltration. Non-volatile sulphate showed reduced infiltration from outdoors. From comparison of outdoor and indoor concentrations of ammonium nitrate and ammonium chloride, which are sensitive to temperature and RH (Lunden et al., 2004), a clear reduction due to phase change was observed upon outdoor-to-indoor transport. We investigated different organic mass spectra for indoor events as recorded in the logbooks. The main events analysed comprised from various types of cooking and candle burning. They showed to emit different proportions of hydrocarbons and oxygenated organic species, which yield $C_xH_y^+$, $C_xH_yO^+$, $C_xH_yO_z^+$ ion classes. The relative intensity of $C_xH_y^+$ ion class out of the total organic signal during frying was 65-68 %, deep-frying ~ 68 %, baking 60-70 %, other forms of cooking 60-68 %, candle burning 60-70 %. For $C_xH_yO^+$ ion class: frying 25-30 %, deep-frying 24-25 %, baking 27-32 %, cooking 25-31 %, candle burning 20-30 %. For $C_xH_yO_z^+$ ion family: frying 7-8 %, deep-frying 7-8 %, cooking and baking 6-9 %, candle burning 6-8 %.

The observed variability in organic mass spectral signature for different indoor sources should allow us to apply Positive Matrix Factorization for source apportionment and processes occurring in indoor air. This will help us to gain a better understanding about main contributors to the observed loading indoors.

This work was financed by the Swedish Research Council FORMAS (Project Dnr 942-2015-1029).

1IA.3

Evaluation of the Molecular Composition of Particle- and Gas-Phase Material in an Indoor Residential Environment using Positive Matrix Factorization. CLAIRE FORTENBERRY, Michael Walker, Audrey Dang, Arun Loka, Gauri Date, Karolina Cysneiros de Carvalho, Glenn Morrison, Brent Williams, *Washington University in St. Louis*

Natural ventilation (e.g., window opening and closing to regulate indoor temperature) promotes infiltration of outdoor pollutants and oxidants into the indoor environment, and infiltrating oxidants like ozone (O_3) can drive formation of new pollutants through oxidative chemistry [1]. Changes in air exchange rates with window opening can also drive volatilization and resuspension of deposited material. Many common indoor air pollutants are semi- or intermediately volatile and therefore actively partition between the gas and particle phases. Because respiratory deposition depends on chemical and physical properties like diffusivity and particle mobility diameter [2,3], greater understanding of pollutant phase partitioning is needed to improve exposure estimates and inform residential building standards.

The Air Composition and Reactivity from Outdoor aNd Indoor Mixing (ACRONIM) field campaign was conducted in the summer of 2016 at a single-family residence in St. Louis, Missouri. A Thermal desorption Aerosol Gas chromatograph (TAG), which pairs automated aerosol collection with thermal desorption and online analysis by gas chromatography-mass spectrometry (GC-MS) [4], was used for chemical measurements of indoor particles and gases. Samples were collected alternately indoors and outdoors with two-hour time resolution throughout the study under three major natural ventilation conditions (all windows closed, one window open, two windows open). A denuder difference method, wherein the TAG sampled alternately through a diffusion denuder and a bypass line, was used to determine the relative contributions of gases and particles to compound abundances.

Using mass spectral databases, we identified approximately 200 compounds in indoor and outdoor ambient TAG samples. A subset of these compounds spanning a range of volatilities and chemical functionalities were integrated, and positive matrix factorization (PMF) analysis was used to identify co-varying compounds across the measurement period. A three-factor PMF solution resolved one indoor factor, one outdoor factor, and one factor corresponding to indoor compounds enhanced with window opening. Compounds loading into the enhanced factor include indoor-originating phthalates and esters common in personal care products, indicating increased volatilization of deposited material with changes in air exchange rate. Loading of acids and aldehydes into the enhanced factor indicate formation of compounds through oxidative chemistry. Higher-factor PMF solutions provide improved resolution of outdoor-originating compounds, including polycyclic aromatic hydrocarbons (PAHs) associated with combustion. Finally, by assessing differences between denuded and undenuded compound abundances, we found that many compounds measured by the TAG in the indoor environment exist significantly in the gas phase, with less than 40% of the inte-grated compounds exhibiting a particle-phase fraction greater than 0.5.

Study of Particulate and Gas-phase Pollutants Emitted from Household and Personal Care Products Under Various Heating and Combustion Scenarios. DONNA AUGUSTE, Shelly Miller, *University of Colorado at Boulder*

In this quantitative research study we investigated fine particle, VOC and PAH emissions from household and personal care products. The products were selected for investigation after Denver-area African American families with asthmatic children identified the products as potential asthma triggers in their homes by using low-cost real-time indoor air quality sensors. We tested the products by using thermal desorption techniques in a controlled lab setting. Because some of the products were selected on the basis of gas-phase pollutants that were emitted when the products were heated or burned, such as hair styling products heated by a flat iron or burned with a butane lighter, we tested the products and documented emissions in a wide range of heating and combustion scenarios. Outcomes of this study may provide data for researchers who are evaluating the impact of household and personal care products on residential indoor air quality for people who are vulnerable due to health conditions.

1IA.5

Characterization of Aerosols in the International Space Station. MARIT MEYER, *NASA Glenn Research Center*

Maintaining good air quality in the International Space Station (ISS) presents unique challenges. Until recently, the environmental monitoring within the ISS has prioritized gaseous constituents. Elevated CO_2 levels and other contaminants were deemed a more immediate health threat to the astronauts who are of excellent health. Although particulate matter (PM) requirements exist, aerosols in the ISS cabin have not been characterized with real-time instruments. NASA's Life Support Systems Project has a roadmap for accomplishing this end goal, which includes intermediate research projects on ISS aerosols. The Aerosol Sampling Experiment was successfully completed in 2017, including sample analysis by microscopy. The re-flight of this experiment in 2018 will provide additional results to compare with the first samples. Additional samples of airborne particulate matter will be obtained in much larger quantities from vacuum cleaner bags. In the absence of gravitational settling, particles are driven by the cabin air flow and deposit on vents and filters of the air handling system. These vents are vacuumed weekly by the astronauts as part of their housekeeping activities. The experiment called Divert Unwanted Space Trash (DUST) will collect debris samples from vents, and vacuum bags will be returned to Earth where various analyses will be performed. This activity also provides the first estimate of PM concentration for ISS cabin air. Plans for a flight experiment with a real-time aerosol instrument are underway, targeting a 2019 launch. Progress of these programs are summarized, along with the latest results from ISS aerosol characterization work.

1IA.6

Indoor Fine and Ultrafine Aerosol Particles Exposure and Its Relationship to the Outdoor Concentrations in Private Homes. Jiangyue Zhao, Birgit Wehner, Thomas Tuch, Kay Weinhold, Maik Merkel, Ulrich Franck, Wolfram Birmili, Anja Lüdecke, Tareq Hussein, Lina Wang, ALFRED WIEDENSOHLER, *TROPOS*

Nowadays people spend a large fraction of their lifetime indoor. Currently, only limited information is available about the exposure of residents to indoor fine and ultrafine particles, which can originate from either indoor or outdoor sources. It is thus important to study the contribution of outdoor sources and residential activities to the indoor air. The efficiency of penetration processes of aerosol particles from outdoor to indoor depends on the particle number size distribution (PNSD), meteorological conditions (e.g. wind speed, temperature), and residential building structure. Therefore, on behalf of the German Environment Agency (UBA), a project to study the indoor aerosol particle exposure and its relationship to the urban and rural atmosphere was granted to the Leibniz Institute for Tropospheric Research (TROPOS).

Measurements are performed in 40 households in two cites of Germany, households are located in the urban, suburban, and rural areas. Each household was or will be probed twice for one week, covering both, the cold and warm seasons. The first measurement period took place in Leipzig in 2017. Measured parameters for indoor and outdoor air have been the PNSD (0.01 – 0.8 µm), using mobility particle size spectrometers (MPSS, designed and build by TROPOS), and PM1, PM2.5, PM10 mass concentrations , using optical particle size spectrometers (Grimm Model 1.108). Additional indoor measurements were the equivalent black carbon mass concentration (microAeth Model AE51), and the indoor CO2 concentration (CO2 sensor, GMP252 Vaisala) to document the room ventilation. The measurements are accompanied by a questionnaire that documents the room characteristics and a digital notebook, capturing the residential activities. During the measurement, a new concept has been designed to determine indoor and outdoor PNSD of fine and ultrafine particles with high quality, as well as measurement of course mode particle mass concentrations. It is designed to perform measurement in multiple private homes over a period of more than one year, to obtain statistically more robust data.

This work presents results from the one-year measurement period in Leipzig, including the variation of particle number concentration (PNC) and I/O ratios in fine and ultrafine particle size ranges, caused by residential activities, as well as the evolution of different indoor particle sources. According to the variation of median of the indoor and outdoor PNCs, the outdoor PNC is generally higher than the indoor one. During nighttime (00:00 - 07:00), both indoor and outdoor PNCs decreased constantly due to less traffic and no indoor emissions. On the other hand, the indoor PNC and I/O ratio show peaks during breakfast, lunch and dinnertime. Ultrafine aerosol particles are especially produced due to cooking activities or candles burning. The 24-h median I/O is in the range of 0.4 to 1, its variation indicate that the indoor aerosol is increasingly decoupled from outdoor during nighttime and during daytime the influence of the outdoor aerosol is more significant (I/O ration close to 1). Black carbon concentrations will be compared to PNC of different size ranges to obtain a better understanding of the black carbon size range from different indoor sources.

1IA.7

Heterogeneous Ozonolysis of Squalene Particles: Gas Phase Products Depend on Water Vapor Concentration. CALEB ARATA, Nadja Heine, Pawel Misztal, Kevin Wilson, Allen H. Goldstein, *University of California, Berkeley*

The oxidation of skin lipids plays an important role in the composition of indoor air. Squalene, $C_{30}H_{50}$, constitutes 10% of the mass of human skin lipids, and contributes 50% of the unsaturated carbon bonds in skin lipids. When exposed to ozone, squalene is quickly oxidized to products spanning a wide range of volatility with some products remaining in the condensed phase while many fragmentation products are released to the gas phase.

Previous work examining the condensed phase products of pure squalene particle ozonolysis in a flow tube reactor found that the rate of squalene ozonolysis was independent of water vapor concentration. However, an increase in water vapor concentration led to lower concentrations of secondary ozonides, increased concentrations of carbonyls, and reduction of particle diameter suggesting water changes the fate of the Crieege intermediate.[1]

To determine if this loss of volume corresponds to an increase in gas phase products, we measured gas phase volatile organic compound (VOC) concentration via proton transfer reaction time-of-flight mass spectrometry (PTR-TOF-MS), a soft chemical ionization technique that allows for quantification of the full suite of oxygenated VOCs which might be expected from these reactions. Our studies were conducted in a flow tube reactor at atmospherically relevant ozone exposure levels (10-30 ppb hr) with pure squalene particles. Along with VOC measurements, the condensed phase composition was measured with vacuum ultraviolet photoionization aerosol mass spectrometry (VUV-AMS) and particle size and number were detected by scanning mobility particle sizer (SMPS).

PTR-TOF-MS measurements indicate that an increase in water vapor concentration leads to a strong enhancement of gas phase oxidation products at all levels of ozone exposure. At high ozone exposure (30 ppb hr), all early generation gas phase products with an unsaturated carbon bond are consumed and known terminal products (acetone, 4-oxopentanal (4-OPA), and succinaldehyde) dominate the gas phase VOC composition across all levels of water vapor concentration. An increase in water vapor from ~3% RH to 70% RH at this high ozone exposure effectively doubles the mass concentration of gas phase products. Even under modest ozone exposure (10 ppb hr), changing water vapor concentration enhances VOC mass concentration by ~70%. At all levels of ozone exposure and water vapor concentration the commonly identified squalene oxidation products (terminal products + 6-methyl-5-hepten-2-one (6-MHO)) account for greater than 75% of the observed mass in the gas phase, and we also detect smaller yields of a complex array of products presumably accounting for the remainder of the mass.

The ability of water concentration to dictate the fate of the Criegee intermediate, and therefore the volatility of the oxidation products, suggests that indoor humidity will affect the concentration of gas phase VOCs emitted from ozonolysis of skin oil. This work also strongly suggests that future heterogeneous alkene ozonolysis experiments should consider the effects of humidity on the products of the reactions.

Emission and Particle Size Distribution of Polycyclic Aromatic Hydrocarbons in Oil Fumes from Domestic Cooking. YU-CHENG CHEN, Kai-Wei Ke, Chin-Yu Hsu, *National Health Research Institutes, Taiwan*

Cooking oil fume is one of the most important components of indoor air pollutants. This study was to investigate the characteristics and emissions of polycyclic aromatic hydrocarbons (PAHs) in cooking oil fumes generated by stir-frying fish. Gas- and particle-phase PAHs with 22 congeners were analyzed by GC/MS-MS. Particle size distribution of PAHs were also evaluated using Micro-Orifice Uniform Deposit Impactors (MOUDI). The mean concentration of total PAHs was 338±16.0 ng/m^3, where gas- and particle-phase PAHs accounted for 93.6% and 6.4%, respectively. 2- to 4-ring PAHs were predominant. PA, FL, and Pyr were the dominant compounds of PAHs in the cooking exhaust. Particle size distribution (MMAD= 1.01 µm, GSD=4.2) showed that PAHs were mainly concentrated in the fine mode with a diameter <2.5 µm, accounting for 67.4%. The emission factors for total PAHs and BaPeq were 11850 and 29.3 ng/kg-fish.

1IN.1: INVITED

Ice Nuclei and Their Impact on Clouds in Alaska. GIJS DE BOER, Matthew Norgren, Jessie Creamean, Amy Solomon, Maximilian Maahn, Fan Mei, Hagen Telg, Allison McComiskey, *CIRES/NOAA*

Northern Alaska is signifcantly influenced by the presence of ice nucleating particles (INP). These particles have a strong impact on hydrometeor properties in the region, introducing influence on cloud radiative properties, precipitation intensity, and cloud lifetime. While critical to the accurate projection of future climate states, the roles of these particles remain a challenge to understand and quantify. The Arctic is particularly sensitive to these interactions because small changes to the impacts of clouds on surface energy exchange can have large implications on a region known for extensive cloud cover whose atmospheric state exhibits large sensitivities to the surface energy budget, and where small shifts in temperature may result in dramatic departures in the surface energy budget through modification of surface albedos. To better understand the role that INP particles play in this puzzle and the sources of aerosols involved, we are using a variety of observational and modeling tools to gain new insight into the importance of these particles.

In this work, we will present observational analyses that shed light on the interplay between aerosols and cloud microphysical and radiative properties in Northern Alaska. Using measurements from surface-based US Department of Energy (DOE) Atmospheric Radiation Measurement (ARM) program observatories at Oliktok Point and Utquiagvik (formerly Barrow) Alaska, together with airborne measurements, we will cover:

[1] Observations of INP in northern Alaska and the potential sources of these particles,
[2] An observational study demonstrating that aerosol loading plays a role in the modulation of precipitation from mixed-phase clouds, thereby impacting surface albedo and cloud dynamics, and
[3] Modeling work demonstrating that small changes to the balance of INP and Cloud Condensation Nuclei (CCN) can impact mixed-phase cloud structure and lifetime.

This combination of studies will highlight the need to further our understanding of INP in this part of the world.

1IN.2: INVITED

Traces of Ice Nucleation Modes in Arctic Mixed-phase Clouds Simulated by a Habit Prediction Scheme. TEMPEI HASHINO, Gijs de Boer, Hajime Okamoto, Greg Tripoli, *Kyushu University*

Ubiquitous and long-lasting Arctic low-level clouds are known to affect the surface energy budget through radiation especially when liquid particles are present (Curry and Ebert 1990, Hashino et al. 2016, Shupe et al. 2011). However, simulation of the mixed-phase status have been challenging partly due to their large sensitivity on ice number concentration (e.g., Morrison et al. 2011, Young et al. 2017). The ice nucleation modes active in the clouds are still open to question (e.g., Fridlind et al. 2007, Paukert and Hoose 2014). In this presentation, we make contrasts of results obtained with three ice nucleation schemes through 3D LES experiments.

A habit-prediction scheme called SHIPS (Hashino and Tripoli 2007, 2008, 2011ab) was implemented in a scalable non-hydrostatic model, UW-NMS (Tripoli and Smith 2014ab). Three ice nucleation schemes are considered: Meyers deposition-condensation freezing, Bigg-type time-dependent immersion freezing parameterization (Bigg), classical nucleation theory based scheme (CNT). For May 7th case during SHEBA campaign, it was found that large cloud droplets in downdraft freeze actively with Bigg. On the other hand, CNT immersion scheme produces much of ice over updraft where supersaturation is relatively high. This means that the initial size of frozen particles is different among the immersion schemes. Through non-linear feedback built in the habit prediction scheme, the resulting aspect ratios of plates clearly differ each other. As a result, radar reflectivity simulated with Bigg scheme better match with ground radar observation although the ice water paths of the two are similar. In the presentation, we will discuss implication of the volume dependence of freezing and formation of the large cloud droplets.

1IN.3

Variations in Ice Nucleating Particle Concentrations at Four Arctic Locations. HEIKE WEX, Lin Huang, Hayley Hung, Rita Traversi, Rebecca J. Sheesley, Claire Elizabeth Moffett, Tate Edward Barrett, Rossana Bossi, Markus Hartmann, Xianda Gong, Frank Stratmann, *Leibniz Institute for Tropospheric Research, Germany*

Filter samples collected on quartz fiber filters at four Arctic measurement stations, Alert, Barrow, Ny-Ålesund and Villum were analyzed with respect to number concentrations of ice nucleating particles (NINP). Measurements were done following the method proposed by Conen et al. (2012), examining immersion freezing: a filter punch (1 mm in diameter) was put into every one of the 96 tubes of a PCR tray, where each tube contained 50 microliter of pure water; the tray was sealed and immersed in the cooling bath of a thermostat and cooled down with a cooling rate of 1K/min; during the cooling, every 6 s a picture of the tray was taken from above, and discrimination between liquid and frozen droplets was done. The obtained temperature dependent freezing curves were used to derive NINP in the temperature range from -5°C down to -20°C.

For Ny Alesund, samples from spring and summer months were examined, while a yearly coverage existed for the other stations. Differing values of NINP were observed during the year, and in general during summer and fall, particles were more ice active than during winter and early spring, indicating that different sources of ice nucleating particles contributed to the panarctic area, their influence varying with season. The lowest values determined for the Arctic samples were about 1 order of magnitude lower than NINP determined from precipitation samples collected in North America and Europe (Petters & Wright 2015), but the highest values were comparable, pointing at a biogenic origin from either the biosphere (e.g., from fungal spores or bacteria) or from marine sea spray (e.g., from algae or bacteria). These biogenic ice nucleating particles might become more abundant as the Arctic warms, with potential influences on cloud properties as e.g., the lifetime of the persistent Arctic stratiform clouds.

This study gives first insights into yearly cycles of ice nucleating particles in the Arctic, but it also reveals open questions and suggests future pathways concerning their examination.

1IN.4

The Concentrations, Spatial Distribution, and Compositions of Ice Nucleating Particles in and around Stratiform Clouds over the Southern Ocean. PAUL DEMOTT, Christina McCluskey, Kathryn Moore, Thomas Hill, Ezra Levin, Cynthia Twohy, Lynn Russell, Darin Toohey, Bryan Rainwater, Greg McFarquhar, Alain Protat, Ruhi Humphries, Gerald Mace, Melita Keywood, Roger Marchand, Cory Wolff, Jeffrey Stith, Sonia Kreidenweis, *Colorado State University*

The Southern Ocean is one of the stormiest places on Earth, and is blanketed in frequent clouds whose properties, phase and lifetime are not well represented in climate models, leading to a high bias in predicted radiation reaching the ocean surface (compared to satellite measurements) over a broad latitude range south of about 55° S latitude. These model biases in turn lead to potentially incorrect predictions of ocean and atmospheric feedbacks. The Southern Ocean Clouds, Radiation, Aerosol Transport Experimental Study (SOCRATES), conducted in January and February 2018 in the region between Hobart, Tasmania and 62° S, provided the most comprehensive assessment of aerosol interactions with supercooled and mixed-phase clouds ever compiled over the Southern Ocean. Studies were specially designed to document primary ice nucleation and its influence on cloud phase. These studies provide constraints for follow on numerical modeling studies to explore primary and secondary (ice “multiplication”) ice formation processes in these clouds.

The NSF/NCAR G-V payload for SOCRATES included two types of ice nucleating particle (INP) measurements, a continuous flow diffusion chamber (CFDC) for real-time INP measurements and bulk volume filter collections for offline immersion freezing temperature spectra measurements. Flight plans were designed to quantify the INP budget around clouds and its potential influence on ice formation in clouds. Typically, measurements were first made of aerosols in ambient air just above supercooled cloud layers (sometimes multiple layers were sampled), and then a level leg was flown within the peak cloud liquid water layer to observe cloud microphysics. Cloud residual particles were sampled with a counterflow virtual impactor (CVI) inlet and the residuals collected for further analysis. Finally, a level leg was flown below clouds in the marine boundary layer (MBL) to sample aerosols coming primarily from sea spray emissions. Both ambient aerosols and cloud residual particles were analyzed to determine INP number concentrations. Aerosol collections for compositional analyses were made from each region around clouds, and from activated INPs from the CFDC. Offline treatments on bulk aerosol samples are also planned to investigate contributions from heat labile INPs and organic INPs. These aircraft data were supported by the same INP measurement suite operated on the Australian Marine National Facility ship, the RV Investigator, leading to comprehensive spatial data on INPs in the Southern Ocean MBL.

INP concentrations over the Southern Ocean region were found to be some of the lowest on Earth, both in the free troposphere and in the MBL. CFDC INP measurements focused at water supersaturated conditions were often at detection limits, well below 1 per liter at -30°C. The particle number concentration enhancement (20-40 times) of the CVI inlet thus permitted best INP detection, as did use of an aerosol particle concentrator on the RV Investigator. INP concentration and compositional data will be summarized, relationships to aerosol properties including bioaerosols will be discussed, and a first comparative inspection of INP versus cloud ice particle concentrations and evolution will be presented.

1IN.5: INVITED

Laboratory Studies on Mechanisms Behind Bacterial Ice-Nucleation Activity. Meilee Ling, Heike Wex, Sarah Grawe, Jonas Jakobsson, Susan Hartmann, Jakob Löndahl, Kai Finster, Thomas Boesen, TINA SANTL-TEMKIV, *Aarhus University, Denmark*

Ice nucleation active (INA) bacteria are one type of atmospheric ice nuclei that have attracted particular attention due to their unique ability to produce specific INA proteins (INprot). Several studies have shown that these proteins are the most efficient ice nuclei known as they induce nucleation at temperatures close to 0°C. We have just started understanding the impacts of aerosolized INA bacteria on atmospheric processes. We present the outcome of a study that focused on elucidating the largely unknown molecular mechanisms behind ice-nucleation induced by INA bacteria.

It is known, that ice nucleation in bacteria is induced by certain proteins. These proteins consist of three parts: N-terminal, C-terminal and the central repeat domain. The central repeat domain is involved in ice-formation and is essential for the protein to function as ice nucleating particle. To understand the role of the central repeat domain of the INprot as well as the role of intermolecular interactions between INprot molecules for their ice-nucleation behaviour, we produced purified recombinant proteins with reducted theoretical ice-binding surface. The native protein that contains 67 amino acid tandem repeats was truncated to only contain 9, 16, and 28 amino acid repeats. The recombinant proteins interacted with bacterial lipids to form particles that are between 30 nm and 100 nm in size. The particle size corresponded roughly with the size of the central repeat domain of INprot.

For one of the INprot constructs that contained 16 repeats (INprot16R), ice nucleation assays were performed using both the Leipzig Aerosol Cloud Interaction Simulator (LACIS) and droplet freezing assays. We found that the truncated bacterial ice nucleation protein was ice active although its ice-binding site was more than 4 times smaller than the sizes of native protein. The onset ice nucleation temperature was between −24°C and −26°C, which strongly indicated that the number of amino-acid tandem repeats determined the ice-nucleation temperature. In addition, we demonstrated that ice nucleation between -9°C to -10°C, which was comparable to the ice-nucleation activity of full-length INprot, was caused by large INprot16R oligomers. These results support previous observations that oligomerization of INprot increases their ice-binding surface, thus changing their freezing behaviour. In conclusion, both the repeat number and the degree of oligomerization contribute in an independent manner to the nucleation mechanism of INA proteins.

1IN.6

Field Collected and Synthesized Proteinaceous Material as Ice Nucleating Particles in Immersion Freezing. NADINE BORDUAS-DEDEKIND, Robert O. David, Kristopher McNeill, Zamin Abdulali Kanji, *ETH Zürich*

Organic aerosols represent a subset of atmospheric particles able to act as cloud condensation nuclei (CCN) and, as more recently found, ice nucleating particles (INPs). CCN and INPs affect the ratio of water and ice in mixed-phase clouds, leading to an impact on Earth's radiative balance. In this work, we use dissolved organic matter (DOM) as a proxy for organic aerosols and lake spray aerosols in ice nucleation experiments. DOM is a complex mixture of terpene-derived compounds, proteinaceous material, lignin, organic acids and some ions. As the dominant IN mechanism in mixed-phase clouds is immersion freezing, we investigated the ability of DOM to act as INPs, using our homebuilt DRop freezing Ice Nucleation Counter Zurich (DRINCZ). We use field collected DOM from American rivers and find that the DOM, despite coming from different locations, shows consistent freezing around –12 °C. We are currently extending these results to field collected snow samples in Switzerland. In addition, we identify the material within DOM responsible for its INP activity. Preliminary results suggest the importance of proteinaceous material and so current work includes synthesis of discrete proteins of different sizes to probe their ice nucleating potential. A laboratory-based chemical perspective to the ability of proteinaceous material to nucleate ice will be presented.

1IN.7

The Importance of Biogenic Material to the Ice Nucleating Particle Concentration in a Coastal Tropical Site. LUIS ANTONIO LADINO, Graciela Raga, Harry Alvarez-Ospina, Manuel Andino, Irma Rosas, Leticia Martinez, Eva Salinas, Javier Miranda, Zyanya Ramirez, Bernardo Figueroa, Erika Quintana, Luis Maldonado, Agustin Garcia, Cédric Chou, Victoria Irish, Allan Bertram, *Universidad Nacional Autónoma de México, Mexico City, Mexico*

Recent studies have demonstrated that oceans can emit aerosol particles with the capability to nucleate ice in clouds known as ice nucleating particles, INPs (e.g., Wilson and Ladino et al., 2015; DeMott et al., 2016; Ladino et al., 2016; and McCluskey, et al., 2017). This is very relevant information that can be included in climate and weather models to predict the formation of ice in clouds given that most of them do not consider the oceans as a source of INPs. There is a need to conduct field measurements in tropical latitudes, since most of the past and recent studies have been conducted in mid- and high latitudes, to understand the role that marine aerosol play in the hydrological cycle and climate of tropical regions.

The present study shows the results obtained in a field campaign conducted in the village of Sisal, located on the coast of the Yucatan peninsula in Mexico (21°09’55”N 90°01’50”O) in January 2017, the first measurements obtained at this tropical site and one of the few data sets at similar latitudes. Aerosol particles around Sisal were found to be very efficient INPs, with onset freezing temperatures as high as -3°C (in some cases), similar to the onsets of Pseudomonas Syringae (Wex et al. 2015) or Arctic sea surface microlayer waters (Wilson et al., 2015).

The results show that the INPs concentration in Sisal is higher than in other studied locations using the same INP counter type. Surprisingly, the air masses arriving in Sisal after the passage of cold fronts reported higher INP concentrations than the average value for the whole sampling period, despite the low total aerosol concentration.

Given the large concentration of INPs at -15°C, it can be inferred that biological particles are very important in ice cloud formation in this tropical location. A variety of microorganism were identified by Gram staining analysis and by detailed bacterial strain isolation. Although the majority are of terrestrial origin, some of them are clearly oceanic, indicating that marine aerosol particles could also play a big role in cloud formation, especially in the presence of cold fronts.

Biogenic Macromolecules from Terrestrial and Marine Biospheres Acting as Ice Nucleating Particles. DANIEL KNOPF, Joseph Charnawskas, Peter Aaron Alpert, Josephine Aller, Swarup China, Daniel Veghte, Daniel Bonanno, Alexander Laskin, Ryan Moffet, Mary Gilles, Jian Wang, *Stony Brook University*

The terrestrial and marine biospheres are sources of ice nucleating particles (INPs) active in the immersion freezing and deposition ice nucleation modes. In regions where mineral dust is scarce, biogenic INPs may control cold cloud formation. Atmospheric particles collected i) in the marine environment including surf zones and Pacific and Atlantic oceans in addition to laboratory mesocosm experiments with natural seawater, ii) above and below the forest canopy in the Amazonian region during the Green Ocean Amazon campaign, and iii) at the ground site of Graciosa Island during the Aerosol and Cloud Experiments in Eastern North Atlantic campaign are examined for their ice nucleation ability. Particles were collected on various substrates for micro-spectroscopic single particle chemical analyses using size-resolved impaction. Ice nucleation experiments were conducted covering temperature and humidity conditions for mixed-phase and cirrus clouds. Experiments were accompanied by scanning electron microscopy with energy dispersive X-ray spectroscopy SEM/EDX for elemental and morphology analyses of particles including INPs, and scanning transmission X-ray microscopy with near edge X-ray absorption spectroscopy (STXM/NEXAFS) for particle mixing state analysis. Additionally, sea spray aerosol (SSA) particles were photospectroscopically examined for the presence of polysaccharidic and proteinaceous matter following chemical analyses.

Analyses of ambient particles including INPs by STXM/NEXAFS show that the organic matter, often present as a coating, is very similar among biogenic particles from different sources. The widespread presence of polymeric carbohydrate molecules is corroborated, in the case of SSA particles, by staining and photospectroscopic analyses. Corresponding ice nucleation experiments with collected particles find that deposition ice nucleation and immersion freezing are initiated under very similar conditions of temperature and humidity. The observations of similar chemical composition and ice nucleation propensity for particles from both the marine and terrestrial biospheres suggest that naturally occurring biogenic polysaccharidic macromolecules from photosynthetic-active plants and phytoplankton form amorphous polymers that may play a role in cloud glaciation under atmospheric conditions. These findings support previous studies showing that ice nucleating macromolecules (INMs), which can be polysaccharides, demonstrate freezing temperatures that correlate with the size of the INMs according to classical nucleation theory.

1MD.1

Verifying the Hygroscopic Particle Growth Model during the Time Relevant to Lung Inspiration. PATRICK O'SHAUGHNESSY, Ralph Altmaier, Ross Walenga, Ching-Long Lin, *University of Iowa*

Under high humidity, hygroscopic compounds attract, absorb, and retain water molecules resulting first in deliquescence, during which the salt core dissolves and a film of salt solution increases, followed by an increase in the resulting droplet solution up to an equilibrium size. The human airways provide an environment suitable for hygroscopic particle growth which will ultimately affect their deposition sites. This research is therefore motivated by the need to accurately determine deposition sites of pharmaceutical compounds that alleviate airway diseases with the use of computational fluid dynamic modeling of the human lung. A set of published coupled differential equations for predicting droplet growth and droplet temperature change were used to predict the growth of sodium chloride particles. Sodium chloride was used as the test substance because its properties to be incorporated into the growth model are well known and accurate. The added effect of salt core dissolution during the initial fast growth phase of the particles was also explored. Differential equations were solved using the MATLAB ordinary differential equation solver function (ODE45). Experimental validation of the model was accomplished with the novel use of video photography to measure frame-by-frame the growth of a salt particle on a microscope slide placed on an inverted light microscope. Using an apparatus containing computer-activated solenoid valves, room air was instantly replaced with air of a known humidity and the subsequent growth of the particle was then videotaped. The numerical model was validated through comparison with the experimental data over the initial 0.2 seconds of growth, consistent with the average residence time needed for transport of air from the top of the trachea to the first lung bifurcation. The experimental data indicated an initial growth phase that is consistent with the model when adjusted to simulate the dissolution of the salt core. This was achieved in the model by holding the solution concentration of the film of salt solution surrounding the salt core at saturation until the droplet grew to have a volume sufficient to hold the entire mass of the original salt particle in solution at saturation. The conventional hygroscopic model then proved to be sufficiently accurate when modeling further growth of the homogeneous salt solution droplet to its equilibrium size. Without incorporating model enhancement to account for salt core growth, the hygroscopic growth model overestimated droplet diameter by an average of 32.1% compared to the measured values during the time span < 0.2 sec. When incorporating salt core growth, the modeled values slightly underestimated droplet diameter by -3.1% over that time span. The deliquescence phenomenon during which the salt core dissolves is therefore a critical component missing from currently published particle growth models. Future research will incorporate this added aspect of the hygroscopic growth model applied to more complex pharmaceutical compounds.

1MD.2

Regional Lung Deposition of Nebulized Hypertonic Saline for Trans-Nasal vs. Oral Inhalation in Healthy, Non-Smoking Adults. WILLIAM BENNETT, Kirby Zeman, Landon Holbrook, Katie Howe, Jihong Wu, David Busick, Richard Boucher, Scott Donaldson, *University of North Carolina at Chapel Hill*

Background: Nebulized, hypertonic saline (7%) (HS) has been shown to improve hydration of cystic fibrosis (CF) airway surfaces, improving both mucociliary clearance and lung function in these patients. We previously demonstrated by gamma scintigraphy that a transnasal Pulmonary Aerosol Delivery device (tPAD; Parion Sciences, Inc., Durham, NC) is able to deliver a HS aerosol to the lungs as efficiently as a standard oral nebulizer (Pari LC Star) but with slightly more peripheral airway deposition as determined by the central/peripheral (C/P) ratio of deposited activity (Zeman et al, J Aerosol Med Pulm Drug Deliv. 30:223, 2017). Because there is uncertainty in the ability for C/P to accurately characterize airway vs. alveolar deposition we speculated that adding insoluble, particle clearance measures post-initial deposition would improve the resolution of aerosol deposition in the various airway generations of the lung.

Methods: Regional deposition for both devices was characterized by measuring the % clearance of inhaled radiolabelled (Tc99m) sulfur colloid particles (in 7% HS) using gamma scintigraphy over 24 h in healthy volunteers (n=5). The traditional C/P ratio was also calculated from the initial deposition image (normalized to a Cobalt57 transmission image for each subject). Airway deposition within bronchial airways (large, intermediate, and small) was estimated as % clearance of the insoluble labeled particles through 24 hours post deposition (Aw). Within the bronchial airways we estimated regional deposition in large airways as % clearance through 3-hour post deposition (LargeAw); large and intermediate airway as % clearance through 6 hours (Large/InterAw); and small airways as the % clearance between 6 and 24 hours (SmallAw). For both inhalation modalities, spontaneous flows/volumes were measured by a pneumotachograph during exhalation. Particle size for the tPAD was designed to be sufficiently small to minimize nasal deposition [volume median diameter (VMD)=1.3 um], and was 3.1 um for the LC Star.

Results: Mean tidal flows and volumes were similar for breathing on the tPAD vs. LC Star, 0.32 vs. 0.24 L/sec and 0.93 vs. 0.80 L. Both devices achieved similar % lung deposition relative to delivered dose, % lung = 30.7 vs. 35.4 for the tPAD vs. LC Star. Percent (%) extrathoracic deposition was also similar = 8.1 (tPAD) vs. 5.7 (LC Star). While the C/P ratios for the initial deposition were not different, 1.16 (tPAD) vs. 1.14 (LC Star), the Aw distribution tended to be less for the tPAD vs. LC Star, 9.7 vs. 21.9% respectively ($p = 0.22$). LargeAw distribution was significantly less for the tPAD vs. LC Star, 2.4 vs. 12.5%, as was Large/InterAw, 2.6 vs. 13.3% respectively ($p < 0.05$ by Wilcoxon signed-rank test). SmallAw distribution was similar between the two devices, 7 (tPAD) and 8.5 (LC Star) %.

Conclusions: The distribution of inhaled aerosol deposition via the tPAD and LC Star appeared to be equivalent using standard deposition measures, e.g., % lung deposition and C/P ratio. However, using measurements of clearance for the deposited insoluble, radiolabeled particles we were able to discern clear differences in regional deposition within large and intermediate airways between the two devices. Such clearance measurements should be considered to provide better resolution for regional deposition of nebulized, aerosolized drug delivery. Supported by NIH P01 HL108808 and Parion Sciences, Inc.

1MD.3

Improved Prediction Of Intersubject Variability In Extrathoracic Aerosol Deposition. Conor A. Ruzycki, Michael Yang, Scott Tavernini, C. Paul Moore, Michelle L. Noga, Andrew R. Martin, Hak-Kim Chan, WARREN H. FINLAY, *University of Alberta*

Orally inhaled aerosols must pass through the extrathoracic region in order to deposit in the lungs. Variability in extrathoracic deposition between different subjects thus leads to variability in the dose delivered to the lungs. The ability to predict such intersubject variability is useful both for risk exposure assessment with inhaled environmental aerosols, as well as in the development of medical aerosol products. Traditional algebraic correlations that were first developed for radiological protection models have been used to predict intersubject variability in extrathoracic deposition. However, these correlations have recently been found to significantly underpredict intersubject variability in mouth-throat deposition. In order to provide more accurate estimates of intersubject variability, we have made use of in vitro data in which we have measured extrathoracic deposition in realistic replicas of the extrathoracic airways of several dozen subjects ranging in age from newborn infants to adults. From this dataset, a theoretical analysis based on uncertainty propagation was developed in order to predict in vivo intersubject variability. To examine the accuracy of these predictions, in vivo measurements of mouth-throat deposition in adults inhaling aerosol during tidal breathing were performed on an independent set of subjects using SPECT scintigraphy. Intersubject variability was found to be in good agreement with our predicted values. For a given aerosol, intersubject variability in extrathoracic deposition is caused by intersubject variations in inhalation flow rate, intersubject variations in geometry captured by a characteristic extrathoracic airway diameter d_c, and intersubject variations caused by geometrical differences in the extrathoracic airways that are not captured by d_c (i.e. geometric dissimilarity). All three factors are found to play a role in causing intersubject variability. The presented methods may be useful to those wanting to predict, understand and control the sources of extrathoracic intersubject variability with inhaled aerosols.

1MD.4

Phenotyping of Chronic Obstructive Disease, COPD, from Deposition Fractions of Inhaled Nanoparticles. JAKOB LÖNDAHL, Jonas Jakobsson, H Laura Aaltonen, Eeva Piitulainen, Per Wollmer, *Lund University, Sweeden*

COPD is one of our most common diseases, globally causing about three million deaths each year and an economic loss of more than two trillion USD. The disease is characterized by poor airflow and shortness of breath, often resulting from smoking or long-term exposure to air pollution. Two major phenotypes of COPD are predominantly bronchial disease with narrowing of the conducting airways, and emphysema, which is damage and enlargement of the terminal airways including the alveoli. A precise diagnosis is important for treatment, but currently there is a lack of cheap and specific methods to diagnose COPD – especially in the form of emphysema.

We have previously suggested that inhaled nanoparticles can be used as a probe to assess dimensions of the small airspaces in the lung (Löndahl et al. 2017). The method, named Airspace Dimension Assessment (AiDA), derives dimensions of the peripheral airspaces from the half-life time of airborne nanoparticles. Enlarged airspaces result in a decreased deposition and hence a longer half-life. The objective of this study was to investigate if AiDA can provide information about emphysema.

AiDA measurements were carried out on 66 subjects: 25 healthy, 23 smokers with COPD and 18 subjects with alpha-1 antitrypsin deficiency (AATD). AATD is a genetic disorder that greatly increases the risk to develop emphysema. This group differs from smokers with COPD, which are likely to have both bronchial disease and emphysema. A comprehensive investigation of lung function was carried out for all subjects, including spirometry, diffusion capacity of the lung for carbon monoxide ($D_{L,CO}$) and forced oscillation technique (FOT). Computed tomography (CT) scans of the chest were made for the smokers and the AATD group.

An instrument for deposition measurements of nanoparticles has been developed as described in detail elsewhere (Jakobsson et al. 2017). Measurements were carried out with 50 nm particles sampled from a volumetric lung depth of 1100-1300 ml after a single breath-hold. To obtain the half-life time of the particles, six measurements were performed for each subject with breath-holds varying between 5-10 s. Data were aggregated into two numbers: an airspace dimension calculated from the nanoparticle half-life and a parameter named intercept, which is related to particle losses in the conducting airways.

In a first analysis of the data, the peripheral airspace dimensions derived from AiDA were 0.27±0.03 mm, 0.37±0.07 mm and 0.34±0.08 mm for healthy, smokers and AATD subjects, respectively. Both groups with disease differed significantly from the healthy subjects ($p<0.001$), which indicate presence of emphysema. The AiDA intercept was 0.50±0.18, 0.33±0.18 and 0.50±0.22, for the three groups: healthy, smokers and AATD. Thus, the AATD group had almost identical intercept as the healthy subjects, while the smokers deviated significantly ($p<0.01$), which imply that the smokers, but not the AATD group, had changes in the conducting airways compared to the healthy subjects. AiDA data correlated significantly with measures of emphysema from $D_{L,CO}$ and CT.

In conclusion, this study shows that AiDA has potential as a new method for detection and phenotyping of lung disease. The method is less expensive than CT and does not involve radiation. It is more specific to lung geometry than $D_{L,CO}$ and is in no need of pressurized CO. Thus, it has ability to be more widely available in healthcare, which would facilitate early discovery of COPD.

Validating CFD Predictions of Small Particle Aerosol Deposition in a Infant Nasal Airway Model. KARL BASS, Susan Boc, Michael Hindle, Worth Longest, *Virginia Commonwealth University*

Nose-to-lung (N2L) administration of enhanced excipient growth (EEG) particles or droplets is expected to increase lung dose and improve targeted delivery of treatments for infants with respiratory diseases, such as Cystic Fibrosis (CF) and Respiratory Syncytial Virus (RSV). With EEG delivery, small particles or droplets (<2µm) enter the nasal cavity via a streamlined nasal cannula and are able to penetrate to the lower airways due to decreased impaction deposition. The hygroscopic excipient of these particles/droplets allows them to absorb moisture in the humid airway conditions and hence increase in diameter, which leads to increased deposition deep in the lungs. The use of CFD and in vitro models has proven a valuable tool to progress the development of the condensational growth approaches for pharmaceutical aerosol delivery. The CFD model must be validated against experimental data to ensure accuracy of the numerical results, and provides greater insight into the transport physics and particle/droplet deposition sites. The objective of this study was to validate mesh and solution parameters against experimental data for accurate modelling of microparticle deposition in an infant nasal airway for the assessment of N2L aerosol administration. The infant nasal model was generated by segmentation of CT scans in the Mimics and 3-matic software packages, and a CAD model developed in SolidWorks. The scan was chosen from an in-house database using selection criteria that are representative of a six-month-old infant: height and weight were between the 25th and 75th percentile, the mouth was closed as is typical during nasal drug administration, and the scan resolution was sufficient to build an accurate model. A Stratasys Objet 24 3D printer was used to build the experimental model, which included connections for the streamlined nasal cannula and outlet filter. A set of CFD meshing and solution guidelines, which were previously developed by our group for aerosol deposition in low Reynolds number and transitional turbulence, were applied to the CFD model in an effort to ensure accurate and reliable results. The CFD model was meshed and transport equations were solved using the capabilities provided by the ANSYS software suite of products with additional in-house user codes to address near-wall turbulence and particle-wall interactions. Comparisons are made between different meshing strategies, such as tetrahedral, cut-cell, and polyhedral cells, mono- and poly-disperse particle size distributions, and laminar or k-omega flow models. Furthermore, a wall roughness model is included to evaluate its accuracy compared to experimental pressure drop, and the effect on the near-wall velocity and turbulence fields. Application of predetermined CFD model guidelines provided results that compared well with experimental deposition data. The results also demonstrate that the two-equation k-omega model is capable of accurately capturing microparticle deposition, without the need for more complex turbulence models. As expected, the low nasal deposition of small EEG particles leads to high lung dose, with more that 90% of particles exiting the experimental and CFD model outlet. This study provides further validation of our previously developed meshing and solution guidelines, with good comparisons drawn between CFD and experimental deposition data in the complexities of an infant nasal model. The CFD model also utilized the wall roughness model, which provides a more realistic representation of the physical characteristics of the in vitro model wall surfaces, and is known to influence the skin friction, pressure drop, and near-wall flow field. For medical applications, the particle deposition data shows that the N2L EEG approach to aerosol delivery provides a highly efficient and targeted method of respiratory drug delivery to infants.

Intranasal and Tracheal Deposition of Dry Particles in 3D Physical Models of Rhesus Macaques. JANA KESAVAN, Valerie J. Alstadt, Jerold Bottiger, Beth Laube, *US ARMY ECBC*

Background: Quantification of particle deposition in the respiratory system of animals is used to assess environmental exposures and the effectiveness of drug delivery. In particular, assessments of toxicological agents and vaccine delivery are often conducted in rhesus macaques and the results are extrapolated to humans. Since rhesus macaques are obligate nose-breathers, it is important to know the percentage of inhaled particles that is lost to deposition in the intranasal airways and trachea and the percentage that is available for delivery to the lungs to make accurate exposure assessments. However, little is known of intranasal and tracheal deposition in rhesus macaques and less is known about dry power deposition in these animals, since most studies are conducted with liquid particles and do not quantify intranasal and tracheal deposition. Because the approval process is long and testing is expensive in live animals, we chose to address this information gap using 3D-printed, anatomically-correct models of rhesus macaques. Methods: Five models were generated from the CT scans of the head and trachea of four female macaques and one male macaque, using 3D-printing technology. The monkeys ranged in age from 3-9 years of age. The models contained the intranasal region (i.e. nasal passage, pharynx, larynx) and the trachea. Deposition fraction was determined using solid polydispersed Arizona Test Dust (ATD) aerosols that contained dry particles ranging in size between 0.5 to 10 microns. Models were individually placed in a chamber and were connected to a vacuum pump that pulled a constant airflow at 2, 4 or 6 L/min through the model. An Aerodynamic Particle Sizer (APS) was used to measure the particle size and the concentration of the test aerosol that entered the nose (upstream aerosol concentration) and exited the trachea (downstream concentration). Approximately 0.06 g of ATD was aerosolized into the chamber and the air was mixed for 45 seconds to obtain uniform aerosol concentration in the chamber. The APS sampled the upstream and downstream aerosol concentrations for 20 seconds. Deposition fraction was calculated for each run by dividing the downstream measurement by the average of the preceding and following upstream measurements. Deposition fraction was expressed as a combination of deposition in the intranasal and tracheal regions. Deposition fraction was plotted as a function of particle size and impaction parameter (diameter squared multiplied by air flow rate). Results: Deposition fraction in the intranasal and tracheal regions combined increased as particle size and/or air flow rate increased and as the impaction parameter increased. Three of the models had similar deposition curves, whereas the other two models had higher deposition curves when the data were plotted as a function of impaction parameter. Deposition efficiency curves for three of the models indicated only 10% deposition for the impaction parameter of 1000 µm2 cm3 s-1. Deposition efficiency curves for the other two models showed approximately 50% and 65% deposition for the same impaction parameter. Conclusions: These findings indicate there was significant variability in the deposition of dry particles in the intranasal and tracheal regions of the 3D-printed models of these rhesus macaques. Such variability suggests there could be significant differences in dry particle deposition in the lungs of these animals as well, which differences could ultimately affect individual animal responses to toxic and therapeutic agents, thereby affecting interpretation of the data. Additional studies using this model approach could provide much needed information about deposition of dry particles in the intranasal and tracheal regions of rhesus macaques, which could lead to more accurate interpretations of toxic and therapeutic environmental exposures, without exposing the animal to the inhaled agents.

1MD.7

In Vitro Determination of Combivent and Spiriva Respimat Dose Delivery in Simulated Spontaneously Breathing Tracheostomy Patients. RYM MEHRI, Abubakar Alatrash, Edgar A. Matida, Fiorenza Frank, *Carleton University, Ottawa, ON, Canada*

Chronic obstructive pulmonary disease (COPD) is a common lung disease that affects the respiratory tract by obstructing the airflow from the lung, hence causing breathing difficulties. Aerosols are commonly used to deliver therapeutic drugs to patient suffering from asthma and COPD. The Spiriva Respimat Soft Mist Inhaler (SMI, Boehringer Ingelheim, Ingelheim, Germany) is capable of delivering a metered dose of aqueous medication (2.5 mcg of tiotropium bromide monohydrate/puff) in the form of aerosols, used in the treatment of COPD. The Respimat SMI is a new generation of inhaler, which generates an aerosol mist suitable for inhalation using mechanical power from a spring in comparison to the liquid-gas propellant typically used in pMDIs. This inhaler was designed to deliver a slow (initial approximate droplet velocity of 10 m/s) but lasting (approximately 1.5 seconds) aerosol mist to facilitate the coordination of actuation with inhalation for proper medication delivery. The inhaled drug efficiency is strongly influenced by the amount of inhaled drug, the aerosol characteristics (particle size distribution), the deposited mass, the delivery method, the flow characteristics and the architecture of airways. For patients with acute or severe COPD, mechanical ventilation is necessary to reduce the patient's work of breathing. In severe cases (unconscious patients), invasive mechanical ventilation is performed using tracheostomy or endotracheal tube, while simultaneously delivering medication. However, the Respimat SMI is not specifically designed to be used in intensive care, greatly affecting the inhaled drug deposition when using mechanical ventilation for patients with tracheostomy or endotracheal tube.

The purpose of this work is to study the aerosol particle deposition, in an experimental set up (in vitro), using a trachea replica (rapid prototyping). The set up attempts to replicate clinical setting for mechanically ventilated patients with COPD via tracheostomy tube. Tiotropium bromide monohydrate is delivered using the Respimat SMI via a spring loaded T-piece connected to an adapter (ODAPT). The ODAPT adapter was previously tested experimentally in continuous flow and using a mechanical ventilator to determine the effect of the adapter and T-piece on medication losses. Using these results, it is possible to properly estimate the medication lost in the ODAPT adapter and T-piece used in the experimental set up.

Human Nasal Olfactory Deposition of Inhaled Nanoparticles. LIN TIAN, Yidan Shang, Jingliang Dong, Kiao Inthavong, Jiyuan Tu, *RMIT University*

Olfactory pathway, susceptible for direct translocation of inhaled nanoparticles into the brain, has been verified in a number of animal studies. The extremely low dose toxic substance strongly suggests subclinical condition that prevents noticeable neurodegeneration until years after prolonged exposure. The exact mechanism, between elevated presence of toxic substances (e.g. heavy metals) and deteriorated neurofunction in human central nervous system, is still not clear; however, nasal olfactory, being portal of the entry for such a transport route, is undoubtedly a critical junction where hint to the time course and dose dependency might be inferred. Using a physiologically realistic nasal and upper airway replica, this study performed human inhalation simulations of nanoparticles (1 to 100 nm) under low to moderate breathing conditions (5 to 14 L/min). Olfactory deposition and the various factors contributing to the process were evaluated. Details on airflow pattern and particle flux in nasal and olfactory were made visible using a 2D unwrapped surface mapping technique, and it was found out that airflow pattern, especially nasal wall shear had a remarkable correlation to particle movement and deposition at the ultrafine scale (< 1~2 nm). Olfactory deposition efficiency was found to be extremely low (< 3.5%), and showed distinctive variation in high diffusivity region when compared to that in the entire nasal cavity. The entrance profile of olfactory deposited particles was seen to be highly selective and unanimously originated from upper section of the nostril near nasal septum. Current study is of significant value to the understanding of human uptake of inhaled nanoparticles through olfactory pathway.

1OF.1

Chlorine and Nitrate Radical Generation in Oxidation Flow Reactors. ANDREW LAMBE, Jordan Krechmer, Ezra Wood, William Brune, Douglas Worsnop, *Aerodyne Research, Inc.*

The majority of oxidation flow reactor (OFR) applications to date involve the generation of hydroxyl (OH) radicals to study daytime multigenerational oxidation of secondary organic aerosol (SOA) precursors. Other atmospheric radicals may also initiate SOA formation, with their relative importance dependent on the specific source region and radical precursor diel profile. Here, we present results from experiments using novel techniques to generate chlorine (Cl) and nitrate (NO_3) radicals in the Aerodyne Potential Aerosol Mass OFR for the study of polluted marine and nighttime source regions, respectively. We provide experimental and model evaluation of Cl and NO_3 generation capabilities as a function of OFR operating conditions. We use proton transfer reaction and chemical ionization mass spectrometer measurements to characterize precursors and oxidation products generated from the Cl and NO_3 oxidation of representative SOA precursors. Finally, we discuss the combined use of OH, Cl and NO_3 radicals to (1) evaluate the fate of known SOA precursors under different atmospheric conditions and (2) constrain the composition of unknown SOA precursors with different OH, Cl and NO_3-initated oxidation rates and SOA formation potentials.

1OF.2

Organic Peroxy Chemistry in Oxidation Flow Reactors and Chambers and Their Atmospheric Relevance. ZHE PENG, Julia Lee-Taylor, John Orlando, Geoffrey Tyndall, Jose-Luis Jimenez, *University of Colorado-Boulder*

Oxidation flow reactors (OFR) are a promising alternative to environmental chambers for investigating atmospheric oxidation processes and secondary aerosol formation. Because of their portability, short residence times, and ability to reach high photochemical ages, they have been increasingly employed in both lab and field studies. However, questions have been raised about how representative the chemistry within OFRs is of that in the troposphere. We investigate the fates of organic peroxy radicals (RO_2), which play a central role in atmospheric organic chemistry, in OFRs, environmental chambers, and under ambient conditions by chemical kinetic modeling. We simulate RO_2 fate in OFRs over a wide range of conditions (both low-NO and high-NO) and compare the results with RO_2 fates in key chamber and atmospheric conditions. For most types of RO_2, their bimolecular fate is mainly RO_2+HO_2 and RO_2+NO, similar to those in chambers and the atmospheric studies. For α,β-substituted primary (SPRO2) and acyl RO_2 (aRO2), RO_2+RO_2 can be significant in RO_2 fate. However, the relative importance of RO_2+RO_2 is sensitive to HO_x recycling ratio of the reaction system. At our best estimate of HO_x recycling ratio (~0.3), RO_2+RO_2 can be the most important bimolecular loss pathway of SPRO2 and aRO2, but still can generally cover the range of the relative importance of RO_2+RO_2 of SPRO2 and aRO2 in chambers and the atmosphere. This is can be explained by HO_2 increased together with OH in OFRs. The OH-to-HO_2 ratio in OFRs covers the ambient values (on the order of 0.01), but can be significantly higher (on the order of 0.1) at high water vapor concentrations, high UV settings, and low precursor concentrations. A low-NO OFR experiments under these conditions could lead to substantial relative contribution of recently proposed, but highly uncertain RO_2+OH to RO_2 fate, much higher than the highest ambient value (~10%). For aRO2, if they do not undergo very fast isomerization in OFRs, they would be substantially (even dominantly) consumed by NO_2 as long as significant amounts of NO precursor(s) are injected into OFRs. $RO_2+NO_2 \rightarrow RO_2NO_2$ is not a sink of aRO2 in chambers and the atmosphere, but it is a sink in OFRs, where the thermal decomposition lifetimes of the product, peroxynitrates (hours), is longer than OFR residence times (minutes). Short residence times of OFRs also prevent RO_2 isomerization in OFRs from proceeding to the same extent as in the atmosphere. Nevertheless, as long as the isomerization of an RO_2 is important in the atmosphere, this isomerization is significant in OFRs, and far from negligible as some researchers have speculated. Overall, chambers generally can obtain atmospherically relevant RO_2 fates; so can OFRs to a large extent. Most importantly, careful attention to OFR (and chamber) operating conditions needs to be paid to simulate specific RO_2 fates, such as avoiding atmospherically irrelevant organic photolysis when increasing VOC concentrations to achieve higher RO_2+RO_2 and/or NO precursor concentrations to achieve higher RO_2+NO.

1OF.3

Modeling the Formation and Composition of Secondary Organic Aerosol in Oxidation Flow Reactors Using Simple and Detailed Chemistry and Thermodynamic Models. Sailaja Eluri, Christopher Cappa, Beth Friedman, Delphine Farmer, SHANTANU JATHAR, *Colorado State University*

Oxidation flow reactors (OFRs) are being increasingly used to study the photochemical production of secondary organic aerosol from both anthropogenic and natural sources. Compared to environmental chambers, OFRs are smaller, easier to operate, allow for much longer photochemical exposures, and are less susceptible to gas and particle wall losses. Yet, there are concerns that high oxidant concentrations and kinetic limitations to gas/particle partitioning may affect the formation and composition of SOA in OFRs. Hence, there is a need to develop and use modeling tools to interpret OFR data and facilitate translation of OFR results to the real atmosphere.

Recently our group reported on experiments that used an OFR to measure the photochemical production of SOA from a diesel engine operated at two different engine loads (idle, load), two fuel types (diesel, biodiesel) and two aftertreatment configurations (with and without an oxidation catalyst and particle filter). In this work, we used two different SOA models, the volatility basis set (VBS) model and the statistical oxidation model (SOM), to simulate the formation and composition of SOA for those experiments. Leveraging recent laboratory-based parameterizations, both frameworks accounted for a semi-volatile and reactive POA; SOA production from semi-volatile, intermediate-volatility and volatile organic compounds (SVOC, IVOC and VOC); multigenerational gas-phase chemistry; and kinetic gas/particle partitioning. Both models suggested that for model predictions of SOA mass to agree with measurements across all engine load-fuel-aftertreatment combinations, it was necessary to model the kinetically-limited gas-particle partitioning in OFRs as well as account for SOA formation from IVOCs. IVOCs were found to account for more than 90% of the model-predicted SOA but accounting for them resulted in an under-prediction of a factor of two for OA atomic oxygen-to-carbon ratios. Model predictions of the gas-phase organic compounds, resolved in carbon and oxygen space, from the SOM compared favorably to gas-phase measurements from a Chemical Ionization Mass Spectrometer (CIMS), substantiating the semi-explicit chemistry captured by the SOM. Model-measurement comparisons were improved on using vapor wall-loss corrected SOA parameterizations but remained insensitive to OFR-specific parameters such as residence time distributions and spatial heterogeneity in oxidant concentrations.

As OFRs are increasingly used to study SOA formation and evolution in laboratory and field environments, models such as those developed in this work can be used to interpret OFR data.

1OF.4

Aging of Selected Particulate Organic Markers in Oxidation Flow Reactors. LIN WANG, Mingyi Wang, Lei Yao, Hangfei Chen, Bowen Zhang, Xiaoyu Hu, *Fudan University*

Aging of organic aerosol particles is one of the least understood topics in atmospheric aerosol research. Here, we used self-made oxidation flow tubes at laminar flow conditions to study OH radical or ozone-initiated aging of selected particulate organic markers, including oleic acid, squalane, and squalene. Pure organic particles were generated via homogeneous nucleation by passing an ultrahigh purity nitrogen over an insulated organic standard and subsequent diluting with zero air. Ozone was produced by photolysis of molecular oxygen using a Hg pen-ray lamp, and OH radical was produced by passing a mixed flow of ozone and water vapor through 254 nm light. We examined gaseous and particulate products by a high-resolution time-of-flight chemical ionization mass spectrometer equipped with a Filter Inlet for Gases and AEROsols (FIGAERO-HRToF-CIMS) using the iodide ion (I-) as the reagent ion. Our results indicate that ozonolysis of an unsaturated particulate species is characterized with formation of high-molecular-weight particulate products through reactions of stabilized Criegee intermediates. On the other hand, OH radical-initiated reactions are featured with multiple reaction mechanisms, especially fragmentation and isomization of the main carbon chain. Our study clearly demonstrates the complexity of atmospheric heterogeneous reactions. A detailed understanding of these mechanisms permits accurate treatment of heterogeneous aging processes in global models in order to better understand the evolution of organic aerosols and to constrain their physicochemical properties including carbon oxidation state, hygroscopicity, and CCN activity throughout their atmospheric lifetime.

1OF.5

A Perspective on Developing “Wall-less” Oxidation Flow Reactors. WILLIAM BRUNE, Andrew Lambe, *Pennsylvania State University*

Environmental chambers and oxidation flow reactors (OFRs) enable the controlled experiments on secondary aerosol (SA) chemistry that are almost never possible in the atmosphere. The experiments provide models with essential quantitative numerical properties such as secondary aerosol nucleation rates, mass yields, chemical composition, hygroscopicity, and optical properties. Unfortunately, the walls of environmental chambers and OFRs can contaminate these experimental results by interacting with the gas-phase and particle-phase chemistry and microphysics. In this presentation, we describe a way to think about developing “wall-less” OFRs and show how the optimal design of each OFR depends on the range of environmental conditions and SA properties to be studied. We provide examples of novel OFR designs and demonstrate the suppression of wall effects compared to conventional OFRs and environmental chambers.

1OF.6

Characterizing Photochemical Environment in the Caltech PhotoOxidation Flow Tube Reactor (CPOT). YUANLONG HUANG, Ran Zhao, John Seinfeld, *California Institute of Technology*

Flow tube reactors have been widely employed to study gas-phase atmospheric chemistry and secondary organic aerosol (SOA) formation. The Caltech PhotoOxidation flow Tube (CPOT) reactor is designed to investigate SOA related gas- and particle- phase photochemical reactions. Hydrogen peroxide serves as the source of hydroxyl radical (OH) under UV radiation. We report here the characterization of the photochemical environment in the CPOT through both experimental and modeling studies. Emphasis will be placed on the influence of the OH-wall interaction and the external OH reactivity (determined with sulfur dioxide and volatile organic compounds) on the photooxidative capacity of the CPOT. We will also present a flow-pattern based method to incorporate the residence time distribution (RTD), which reflects the fluid mechanical non-ideality of the reactor, into both data interpretation and model simulation.

1OF.7

Secondary Aerosol from Gas Emissions of Sage (SAGES): Characterizing SOA Production from Coastal Sage Scrub Plant Emissions under High and Low NOx Conditions. CELIA FAIOLA, Chinmoy Sarkar, Jordan Krechmer, Archit Mehra, Leah Williams, Fatemeh Khalaj, Manjula Canagaratna, Alex Guenther, Dasa Gu, Arin Boghoz, Angelo Calinga, John Jayne, Douglas Worsnop, Andrew Lambe, *University of California Irvine*

Plants emit more than 1,700 different volatile compounds, but very few of these compounds have been the subject of systematic SOA laboratory studies. It is unclear if a complex mixture of plant volatiles will generate SOA in a predictable way based on a linear combination of the individual components. Furthermore, it is unclear if the handful of proxy compounds that have been used in most SOA lab studies adequately represent the SOA chemistry of real plant emissions containing unique compounds that have not been studied previously. Thus, there are two major gaps in SOA studies: 1) investigations of realistic complex VOC mixtures and 2) investigations of plant volatiles that have not been the subject of previous lab studies. We addressed these two critical gaps by exposure of Salvia mellifera (black sage) and Artemisia californica (california sagebrush) emissions to O3, OH, and NO3 in the Aerodyne Potential Aerosol Mass oxidation flow reactor. These plants are keystone species in the Southern California coastal sage scrub ecosystem. SOA production was observed via OH exposure under low- and high-NO conditions, but not via O3 or NO3 exposure. The plant emissions and ensuing SOA formation were dominated by compounds that have not been targeted in previous SOA studies, including oxygenated monoterpenes such as camphor, 1,8-cineole, and alpha-thujone. For comparison to the mixture, these three compounds that dominated emissions from black sage were individually exposed to OH radicals. Gas-phase emissions were characterized with GC-ToF-MS and a Vocus PTR-MS, which also measured oxidized products. Particle size distributions and composition were characterized with a scanning mobility particle sizer and an HR-LToF-AMS. An overview of the experiments will be presented including detailed plant emission profiles, SOA yields, and SOA composition.

1OF.8

Real-time and Off-line Applications of Oxidative Flow Reactor (OFR) for Chemical and Physical Characterization of Secondary Organic Aerosols (SOA). YONG JIE LI, Pengfei Liu, Qi Chen, Yan Zheng, Xi Cheng, Keren Liao, Scot T. Martin, *University of Macau*

Secondary organic aerosols (SOA) are major components in atmospheric particulate organic matters. The chemical and physical properties, as well as their dynamic evolution, are crucial in our understanding of the impacts of SOA. Fundamental investigations on SOA are usually done with large-scale smog chamber facilities (SCF) or small-scale oxidative flow reactors (OFR). The flexibility of OFR makes it an attractive alternative to SCF for SOA studies. Lab-based or field-based OFR studies have offered new insights in SOA from a variety of precursors (Lambe, et al., 2011, Lambe, et al., 2012) and in different environments (Hu, et al., 2016, Palm, et al., 2018) using real-time characterization. Apart from real-time approaches, sampling of SOA after OFR for off-line analysis or processing can also be used to study different aspects of SOA properties. We will present applications of OFR for characterization of SOA using both real-time and off-line approaches. Physical and chemical characteristics of SOA from different precursors were obtained before and after exposure to gaseous ammonia to study the effects of phase state on SOA reactivity (Li, et al., 2015). A lot more characterization can be applied to SOA samples collected by either conventional filter sampling and/or thin-film formation using an electrostatic precipitator (Liu, et al., 2013). SOA collected on an attenuation total reflection (ATR) crystal aged with ammonia was investigated with Fourier transfer infrared (FTIR) spectroscopy; browning of SOA by ammonia was studied with UV-vis spectrometry (Liu, et al., 2018); evaporation kinetics and hygroscopicity were measured for the SOA film using a quartz crystal microbalance (QCM) (Liu, et al., 2016, Liu, et al., 2018). To extend these real-time and off-line applications of OFR in high-NOx conditions commonly found in urban environments, OH exposure calibration results for OFR185 and OFR254 with or without N2O injection will also be presented.

Measured Contributions to Cloud Condensation Nuclei from DMS and Sea Spray in the Marine Atmosphere. Kevin Sanchez, Chia-Li Chen, LYNN RUSSELL, Raghu Betha, Jun Liu, Derek Price, Paola Massoli, Luke Ziemba, Ewan Crosbie, Richard Moore, Markus Müller, Sven A. Schiller, Armin Wisthaler, Alex Lee, Patricia Quinn, Timothy Bates, Jack Porter, Thomas Bell, Eric Saltzmann, Robert D. Vaillancourt, Michael Behrenfeld, *Scripps Institution of Oceanography*

Biogenic sources contribute to cloud condensation nuclei (CCN) in the clean marine atmosphere, but few measurements exist to constrain climate model simulations of their importance. The chemical composition of individual atmospheric aerosol particles showed two types of sulfate-containing particles in clean marine air masses in addition to mass-based Estimated Salt particles. Both types of sulfate particles lack combustion tracers and correlate, for some conditions to atmospheric or seawater dimethyl sulfide (DMS) concentrations, which means their source was largely biogenic. The first type is identified as New Sulfate because their large sulfate mass fraction (63% sulfate) and association with entrainment conditions means they could have formed by nucleation in the free troposphere. The second type is Added Sulfate particles (38% sulfate), because they are preexisting particles onto which additional sulfate condensed. New Sulfate particles accounted for 31% (7 cm-3) and 33% (36 cm-3) CCN at 0.1% supersaturation in late-autumn and late-spring, respectively, whereas sea spray provided 55% (13 cm-3) in late-autumn but only 4% (4 cm-3) in late-spring. Our results show a clear seasonal difference in the marine CCN budget, which illustrate how important phytoplankton-produced DMS emissions are for CCN in the North Atlantic.

1RA.2

South African Biomass Burning Season Aerosols Observed over the Remote Southeast Atlantic Ocean on Ascension Island. Allison Aiken, Paquita Zuidema, Arthur J. Sedlacek, THOMAS WATSON, Stephen Springston, Connor Flynn, Chongai Kuang, Janek Uin, Manvendra Dubey, *Los Alamos National Lab*

Biomass burning (BB) emissions are a large source of carbon to the atmosphere via particles and gas phase species. With a potential rise in drought and extreme events in the future, these numbers are expected to increase. From approximately June-October every year, the plume of South African BB emissions, the largest BB source in the world, are advected west and are known to impact both the boundary layer and free troposphere at Ascension Island (Zuidema et al., 2016). Ascension Island is located 8 degrees South of the Equator and 15 degrees West Longitude in the middle of the South Atlantic Ocean, at least 1000 miles from any major shoreline and closest to the continent of Africa. During the U.S. DOE ARM field campaign, Layered Atlantic Smoke Interactions with Clouds (LASIC), direct online in situ measurements of aerosol and trace gases were collected continuously on Ascension Island from June 2016 through October 2017 spanning a ~1.5 year period. While low Southern Hemisphere background aerosol and trace gas measurements are observed most of the year that picture changes during the South African BB season.

Two BB seasons are contrasted with the near pristine background conditions during the campaign from the ARM Aerosol Mobile Facility 1 (AMF1) and Mobile Aerosol Observing System (MAOS). Refractory light absorbing carbon mass concentrations reach 1 μg m-3 during multiday plumes and exceed 25% of the total aerosol submicron mass concentration, contrasting significantly with BB plumes observed over the Southwestern United States (SW US) and South America (Brazil). Numerous direct in situ aerosol and trace gas measurements are presented, e.g. submicron non-refractory chemical composition (Organics, Sulfate, Nitrate, Ammonium, Chloride), refractory soot, PM1 and PM10 aerosol absorption and scattering, carbon monoxide (CO), etc. Aerosol and trace gas signatures are investigated along with backtrajectories to identify sources. Carbonaceous aerosols emitted with gas-phase CO are used to determine particulate emission ratios along with intrinsic and extrinsic aerosol properties.

Comparison will be made between the aerosol species observed during LASIC versus BB from wildfires measured in the SW US and Brazil. Results from single fuel laboratory studies probed with aerosol mass spectrometry alongside aerosol optical properties will also be presented contrasting near source and far field BB emission profiles. Organic Aerosol (OA) to refractory soot ratios of ~2.4 observed in the BB plumes from South Africa on Ascension Island are much higher than BB emissions sampled from forest fires in the SW US and BB sources in Brazil. The differences observed between BB emissions in different regions highlights the need to further understand the different atmospheric chemistries within the context of the differing background conditions in the two hemispheres, including differences in BB fuel types and combustion conditions.

Marine Boundary Layer Aerosol in Eastern North Atlantic: Seasonal Variations and the Key Controlling Processes.

GUANGJIE ZHENG, Tamara Pinterich, Allison Aiken, Robert Bullard, Edward Luke, Pavlos Kollias, Chongai Kuang, Stephen Springston, Janek Uin, Thomas Watson, Rob Wood, Jian Wang, *Brookhaven National Laboratory*

The response of marine low cloud systems to changes in aerosols represents one of the largest uncertainties in climate simulations. Major contributions to this uncertainty derive from poor understanding of aerosol under natural conditions and the perturbation by anthropogenic emissions. The Eastern North Atlantic Ocean (ENA) is a region of persistent but diverse marine boundary layer (MBL) clouds, and whose albedo and precipitation are highly susceptible to perturbation in aerosol properties. In this study, we examine aerosol properties, trace gas concentrations, and meteorological parameters measured at the ARM ENA site on Graciosa Island since 2014. Aerosol size distribution from 55 nm to 1 µm typically consists of three modes: Aitken (At), Accumulation (Ac) and Sea Spray Aerosol (SSA) modes. Observed CCN number concentrations are in general agreement with the sum of Ac and SSA mode concentrations. The number concentration of SSA mode, mainly driven by sea spray aerosol (SSA) production and precipitation scavenging, is higher in winter and lower during summer. The entrainment of free tropospheric aerosols, including long range transported continental pollution, represents a major source of At and Ac mode particles. In comparison, SSA often contributes to a minor fraction of At and Ac mode number concentrations, with estimated mean annual contribution around 4.5% and 21%, respectively. For the combined population of At and Ac mode particles, coalescence scavenging represents the major sink, while coagulation of At mode particles with Ac and SSA mode particles and activated droplets inside clouds can also play a role. Higher contribution of entrained free tropospheric aerosol is coincident with stronger precipitation during spring and winter seasons. As a result, At and Ac mode number concentrations exhibit weak seasonal variations, with slightly higher levels during the spring and summer seasons.

1RA.4

Free Tropospheric Aerosol characteristics over the North Eastern Atlantic Ocean and Its Relationship to the Marine Boundary Layer. BIRGIT WEHNER, Karine Chevalier, Silvia Henning, Kay Weinhold, Oliver Welz, Claudio Mazzoleni, Paulo Fialho, Simeon Schum, Stefano Viviani, Greg Roberts, *Leibniz-Institute for Tropospheric Research*

Networks for continuous ground based measurements of aerosol particles have been established over the last decade. However, most of the measurement sites are located on continental areas and are not representative of marine regions. Roughly, 70% of Earth's surface is covered by water and thus, the knowledge of climate-relevant parameters such as aerosols, clouds and radiation also in marine regions is of high importance to understand the global climate.

Although the marine boundary layer structure over the oceans is considered simpler compared to continental boundary layers, decoupled layers with several levels often characterize the stratification. This system is not well understood up to now, for cloudy as well for cloud-free situations.

The ACORES campaign (Azores stratoCumulus measurements Of Radiation, turbulEnce and aeroSols) has been performed in July 2017 in the Azores, in the Atlantic Ocean. The overarching goals of the project was the detailed study of the stratification of the marine boundary layer in terms of clouds and aerosol properties. Besides helicopter-borne vertical measurements, this study comprises also ground-based measurements at sea level (ARM site ENA) and in the free troposphere (UAc site OMP - Pico Mountain Observatory, 2225 m).

Aerosol Particle number size distribution measurements between 10 nm and 10 µm at both sites (ENA and OMP) have been performed using a Mobility Particle Sizer System (MPSS) and an Aerodynamic Particle Sizer (APS) over 3 weeks in July 2017. In addition, a mini cloud condensation nuclei counter (CCNc) has been operated in flow scanning mode at the OMP site. Furthermore, measurements of aerosol scattering and absorption coefficients (or black carbon, BC), as well as meteorological data, are available.

A number of ground-based aerosol and meteorological, as well as remote sensing data completed the measurements at ENA (https://www.arm.gov/capabilities/observatories/ena).

During this campaign, we measured for the first time on Pico Mountain, particle number size distributions down to 10 nm and CCN concentrations. The data have been investigated for special features, such as new particle formation or long range transport of polluted air masses. The summer 2017 was relatively clean compared to earlier years and the number concentration of larger particles (> 100 nm) has been relatively low, as confirmed by low BC concentrations. Only two periods with slightly increased BC values have been observed, but values were still below 40 ng m^{-3}.

The aerosol number concentrations have been relatively low over the whole period, while small plumes, obviously caused by local anthropogenic pollution, often influenced the ENA site.

During nighttime, Pico Mountain was five times inside a cloud, i.e. the relative humidity was 100% and particles larger than 50 nm, as well as CCN, were completely removed, while smaller particles were still detected as interstitial aerosol.

On one day out of three weeks, new particle formation on Pico was observed while there was no clear event visible at ENA.

On the majority of measurement days, the particle number size distribution at sea level consisted of two modes. Instead, the particles in the FT showed typically only one mode, but, contradictory to previous studies, this mode occured in the Aitken mode range (< 100 nm) but also above 100 nm, i.e., in the accumulation mode, originated probably from long-range transport.

Molecular and Physical Characteristics of Aerosol at a Remote Marine Free Troposphere Site: Implications for Atmospheric Aging. SIMEON SCHUM, Bo Zhang, Katja Dzepina, Swarup China, Paulo Fialho, Claudio Mazzoleni, Lynn Mazzoleni, *Michigan Technological University*

Marine regions cover a large fraction of the Earth's surface. In these regions, long range transported aerosol can play a key role on the Earth radiative balance by interacting with clouds and solar radiation. However, free tropospheric aerosol over the ocean are not well characterized due to the challenges of sampling in these remote areas. We analyzed the molecular and physical characteristics of long-range transported aerosol samples collected at the Pico Mountain Observatory (38° 28′ 15′′ N; 28° 24′ 14′′ W, 2225 m above mean sea level) in the North Atlantic Ocean. The Observatory is located in the marine free troposphere on Pico Island in the Azores archipelago, making it an excellent site for the study of aged organic aerosol with minimal influence of local emission sources. Specific samples were selected for detailed molecular study based on (1) elevated organic carbon concentrations and (2) FLEXPART simulations with the goal to capture pollution events of different origins. Water-soluble organic aerosol extracts were then analyzed using ultrahigh resolution mass spectrometry ($R > 200{,}000$) in order to elucidate their molecular characteristics. Thousands of molecular formulas were assigned to each of the individual samples. On average ~60 % of the molecular formulas contained only carbon, hydrogen, and oxygen atoms (CHO), ~30 % contained nitrogen (CHNO), and ~10 % contained sulfur (CHOS). In general, samples transported through the free troposphere were less oxidized than those transported through the boundary layer. Despite their longer residence times, average oxygen to carbon (O/C) ratios of less than 0.5 were observed for the free tropospheric aerosol, compared to O/C ratios greater than 0.5 for those transported in the boundary layer. Using the extracted ambient temperature and relative humidity from the FLEXPART-GFS/FNL simulations, the phase state of the water-soluble organic aerosol molecular species was estimated for up to 5 days before sampling. The low temperature and relative humidity in the free troposphere predict a solid phase for the organic aerosol, which likely increased its resistance to oxidation. The specific molecular differences in the overall oxidation between the free tropospheric transported aerosol and the boundary layer transported aerosol are presented, as well as the potential for aqueous phase oxidation and differences in the aerosol phase state.

Aerosol Particle Size Distributions and Compositions over the Southern Ocean in the Austral Summer of 2017.

TAKUMA MIYAKAWA, Fumikazu Taketani, Masayuki Takigawa, Chunmao Zhu, Kazuhiko Matsumoto, Yutaka Tobo, Momoka Yoshizue, Yugo Kanaya, *Japan Agency for Marine-Earth Science and Technology*

Aerosol particles in the marine boundary layer are emitted from the ocean surface through the sea-spraying process. They can affect the cloud formation over the ocean, resulting in their significance in the Earth's radiative budget, because the ocean aerial coverage is high on the earth. Southern Ocean (SO) is a unique region with rich ecosystems and without anthropogenic and continental natural impacts especially in austral summer (e.g., McCoy et al., 2015). To the best of our knowledge, the measurements of aerosol particles over the Pacific Ocean sector of SO are sparse and critically needed for understanding the concentration levels of aerosols to assess the role of aerosols as cloud condensation nuclei (CCN) in this region.

We have conducted ship-borne aerosol measurements using our research vessel "*Mirai*" in a framework of the research cruise "Trans South Pacific Project" between Japan and Chili (December 27, 2016-March 28, 2017). This cruise consisted 4 legs. RV "*Mirai*" was deployed over the SO (from Punta Arenas, CHL to Auckland, NZ) during the third leg in the late austral summer of 2017 (February 10-March 3, 2017). We have performed in-situ measurements of size distributions of total and non-volatile (at 300ºC) aerosol particles using a scanning mobility particle sizer (SMPS, TSI, the combination of a differential mobility analyzer model 3080 and a condensation particle counter model 3010), black carbon aerosol using a single particle soot photometer (SP2, DMT), and fluorescent bioaerosol particle (FBAP) using a wideband integrated bioaerosol sensor (WIBS4A, DMT) on the experimental room located on the upper level of RV Mirai. In the third leg, we performed air sampling for the post analyses of chemical composition, morphology (microscopy), and ice nucleating particles.

During the cruise of third leg, air masses without continental impacts were successfully observed except selected periods. We here assume the major source of aerosols in the MBL is the surface of the SO. Our observation results indicated that aerosol particles had the bimodal size distributions over the SO, which is commonly found in the MBL in a plenty of previous studies (e.g., Hoppel et al., 1990). The minimum diameter among two modes, so called Hoppel minimum (D_{HO}), was around 70 nm on average, which can be used for estimating the supersaturation SS level in the cloud process with the assumed chemical composition (Hoppel et al., 1986). The estimated value of SS varied from 0.2-0.4% with the assumption of pure ammonium sulfate during the cruise. We will present the temporal variations of size-segregated aerosol concentrations, CCN-proxy (particles larger than D_{HO}, e.g., Clarke and Kapustin, 2010), volume-fraction-remaining (VFR) at 300ºC as a diagnosis of the sea-salt particle impacts, FBAP, and the chemical composition (organic carbon) to elucidate the atmospheric physics and chemistry of natural aerosols in this region.

Seasonal Variability of Aerosol Optical and Physical Properties from the Eastern North Atlantic (ENA) Aerosol Observing System (AOS) during 2016 and 2017. FRANCESCA GALLO, Allison Aiken, Connor Flynn, Annette Koontz, Jian Wang, Guangjie Zheng, Stephen Springston, Chongai Kuang, Janek Uin, Eduardo Azevedo, Kim Nitschke, *Los Alamos National Lab*

In the present study we assess the seasonal variability of aerosol optical and physical properties at the Eastern North Atlantic (ENA) Atmospheric Radiation Measurement (ARM) Facility. The ENA site is located in the remote Azores archipelago and is subject to strong meteorological variability during the year. Consequently, aerosol composition and concentration are affected by these meteorological variations. Especially, the combination of midlatitude, tropical and extratropical cyclones and strong surface wind speeds affect the Region during the winter, leading to the formation of coarse mode aerosols (e.g. sea salt), meanwhile the subtropical Azores high pressure system and diminished surface wind speeds in the summer lead to the production of fine mode aerosols. Here we show the seasonal variability of aerosol absorption, scattering and extinction coefficients (B_{abs}, Bsca and Bext) and intensive aerosol properties of light absorption, scattering and extinction Angstrom exponents (AAE, SAE and EAE) and single scatter albedo (SSA) for submicron (PM_1) and sub-10 µm (PM_{10}) diameter size cuts during the years 2016 and 2017 at ENA. Data were obtained through continuous measurement with the Aerosol Observing System (AOS) equipped with a 3 wavelength Nephelometer (450, 550, 700 nm) and PSAP (464, 529, 648 nm). Results indicate a seasonal trend in the PM_1 and PM_{10} aerosol optical properties during the period of study with the exception of PM_{10} SSA (0.90 ± 0.09). Total aerosol B_{abs} is dominated by the PM_1 fraction throughout the year (~60% of the total B_{abs} due to the submicron) while B_{sca} is dominated by the supermicron species (~ 70% of the total B_{sca} due to the PM_{10}). However, both B_{abs} and B_{sca} are highest in the winter and lower in the summer ranging respectively from seasonal averages of 0.46 – 0.70 Mm^{-1} and 5.35 – 7.38 Mm^{-1} in PM_1 and 0.77 – 1.15 Mm^{-1} and 14.8 – 26.57 Mm-^{1} in PM_{10}. B_{ext} shows seasonal variability in the PM_{10} fraction (seasonal averages ranging from 12.71 – 19.65 Mm^{-1}). Intensive aerosol properties also indicate a seasonal trend: while AAE is highest in the winter (seasonal averages ranging from 0.85 – 1.09 in PM_1 and from 0.96 – 1.12 in PM_{10}), SAE is highest in the summer (seasonal averages ranging from 1.88 – 1.18 in PM_1 and from 0.39 – 0.89 in PM_{10}). Combination of AAE and SAE spectral variability in PM_1 reveals the dominance of small particle diameters in the summer and the presence of mixed absorption species, dominated by soot in the winter. Changes in both meteorological conditions and emission source through the year could explain these variations. This hypothesis is also supported by the evaluation of wind speed and direction and total aerosol number concentration. Future investigations concerning aerosol size distributions from the UHSAS and chemical composition from the ACSM at ENA will be used to support our findings.

Variations in Composition of Particles Sampled at Different Altitudes in the North Atlantic. DANIEL VEGHTE, Swarup China, Joseph Charnawskas, Daniel Bonanno, Johannes Weis, Ryan Moffet, Mary Gilles, Daniel Knopf, Jian Wang, Alexander Laskin, *Pacific Northwest National Laboratory*

Atmospheric particles collected at varying altitudes in the remote region of the Azores archipelago were characterized using chemical imaging techniques. The particle samples were collected during the Aerosol and Cloud Experiment in the Eastern North Atlantic (ACE-ENA) field study, onboard the ARM aerial facility platform (G-1 aircraft) and at the ground ENA supersite. The ground site collection allowed for size resolved collection of aerosol particles at sea level utilizing a multistage impactor while sampling aboard the aircraft employed a custom built time resolved aerosol collector. Multi-modal chemical imaging of particles was performed using complementary capabilities of electron microscopy and scanning transmission X-ray microscopy. Additionally, high resolution mass spectrometry was used to characterize the chemical composition of the organic fraction of collected particles. In additional experiments, collected particles were investigated by in-situ electron microscopy to determine volatility, ice nucleation activity, and water uptake on a single particle basis. Particle sources in the marine environment include regional sea spray, new particle formation, and long-range transport among others. This work demonstrates the impact of different marine aerosol particles collected at distinct layers of the atmosphere through chemical characterization as well as simulating particle properties during the processes of water uptake and ice nucleation.

2AC.1

Organic Aerosol from Chlorine-Initiated Oxidation of Hydrocarbons. LEA HILDEBRANDT RUIZ, Dongyu S. Wang, Surya Venkatesh Dhulipala, Sahil Bhandari, Catherine Masoud, Kanan Patel, *University of Texas at Austin*

Chlorine atoms (Cl) are much more reactive than hydroxyl (OH) and ozone (O_3) and can oxidize functional groups or whole molecules that are resistant to OH and O_3. Cl can also initiate radical propagation pathways which generate OH as secondary radical. Thus, Cl can rapidly initiate the oxidation cascade that results in the formation of organic aerosol (OA). Tropospheric chlorine chemistry has not received as much attention because its importance was believed to be limited to coastal areas. However, recent ambient measurements have detected high concentrations of reactive chlorine species in inland and mid-continental regions, suggesting that chlorine chemistry is also important in continental regions. In addition, due to its use as a disinfectant, chlorine chemistry can be important in the indoor environment.

Here we summarize results from laboratory experiments conducted in our group, which show efficient formation of OA from chlorine-initiated oxidation of different hydrocarbon precursors including isoprene, toluene, butyl carbitol and alkanes. Using measurements from a high resolution time of flight chemical ionization mass spectrometer (CIMS), we have tracked several generations of oxidation chemistry leading to the formation of organic particulate matter. We measured known and identified previously unknown reaction products of Cl-initiated oxidation, including highly oxidized molecules (HOMs). Using a filter inlet for gases and aerosols (FIGAERO) we analyze the molecular composition of organic aerosol and have found that Cl-initiated oxidation can form larger and lower-vapor pressure compounds than OH-initiated oxidation, which likely contributes to the larger aerosol mass yields often observed from Cl-initiated chemistry. OA formed from Cl-initiated reactions is often also more oxygenated than OA formed from OH-initiated chemistry.

The fast reaction rate of Cl with hydrocarbons enables complete consumption of all hydrocarbon precursors, including toluene, during an environmental chamber experiment. We evaluated the aging of toluene SOA by adding oxidant precursors after all toluene had been consumed. The addition of oxidants did not result in a significant change in the OA oxidation state, suggesting that the system may have reached an oxidative end-point in the particle phase. Organochlorides formed from all precursors investigated, even when the initial oxidation occurred via hydrogen-abstraction. Overall, our data suggest that chlorine chemistry can enhance atmospheric reactivity and increase the formation and transformation of organic aerosol. Cl-initiated formation of OA is currently not represented in air-quality models used to support the development of environmental policies; we argue that it should be.

2AC.2

Formation of Highly Oxidized Multifunctional Organic Compounds from Chlorine Atom Initiated Oxidation of α-pinene. Yonghong Wang, MATTHIEU RIVA, Xie Hongbin, Liine Heikkinen, Simon Schallhart, Otso Peräkyla, Chao Yan, Markku Kulmala, Mikael Ehn, *University of Helsinki*

Highly oxygenated molecules (HOMs) from the oxidation of monoterpenes in the atmosphere can irreversibly condense onto particles and contribute to secondary organic aerosol formation. Recently, the formation of nitryl chloride (ClNO2) from heterogeneous reactions, and subsequent photolysis, to produce chlorine atoms is suggested to be extensive not only in coast area, but also in urban region. However, the oxidation of monoterpenes such as α-pinene by chlorine radicals has received very little attention, and the ability of this reaction to form HOMs is completely unstudied. Here, chamber experiments were conducted with a-pinene and chlorine gas under low NO and high NO conditions, respectively. A NO3-based CI-APi-L-TOF was used to measure highly oxidized products. Clear distributions of monomers with 9-10 carbon atoms and dimers with 18-20 carbon atoms were observed under low NO conditions. With increased concentration of NO in the chamber, the formation of dimers was suppressed due to the competing reactions of peroxy radicals with NO. We calculated the HOM yields from chlorine-initiated oxidation of a-pinene under low NO conditions, while the yield at high NO could not be determined because of interference from ozone produced from the NOx, which subsequently reacted with a-pinene. Our study demonstrates that chlorine radical initiated oxidation of a-pinene will produce low volatility organic compounds, such as HOMs, which indicates that autoxidation processes in chlorine radical oxidation of a-pinene can be important. Further analysis will provide insights on the expected importance of the studied reactions in the atmosphere.

2AC.3

Probing the Role of Water in Criegee Chemistry Leading to High Molecular Weight Compounds on Aqueous Organic Surfaces. LIJIE LI, Michael Hoffmann, Agustin Colussi, *California Institute of Technology*

Ozonolysis of unsaturated organic gas emissions is a fundamental process in the formation and growth of tropospheric aerosols. O_3 adds to olefinic double bonds to produce chemically activated ozonides, which decompose into reactive carbonyl oxide Criegee (CIs) intermediates. CIs can react with H_2O, SO_2, carboxylic acids, aldehydes and alcohols, undergo unimolecular isomerization and dissociation, or bimolecular self-reaction. The competition among different reaction pathways determines the fate of organics and their potential for aerosol formation and growth. Understanding the role of water in these processes is essential, given its pervasiveness in the atmosphere both in the gas and aerosol phases. Recent reports have pointed out that the fate of gas-phase CIs in the troposphere is in fact dominated by their reactions with (H_2O)n_clusters. The ozonolysis of low-volatility, hydrophobic vapors, however, largely takes place on air-aerosol interfaces, given their fast reactions with O_3(g) and the low solubilities of both reactants in water. It is important to realize that in the steep water density gradient at air-aerosol interfaces, chemistry may proceed along different pathways and at faster rates than similar reactions in bulk gas and aerosol phases. In this work, we investigate the roles of water in the ozonolysis of oleic acid (OL) at the aerial interface of aqueous aerosols.

We focused on the formation of high molecular weight (HMW) compounds during the interfacial ozonolysis of OL. OL dissolved in acetonitrile/water mixtures (AN/W) was exposed to O_3(g) for < 50 µs under atmospherically relevant 1 atm of N_2, 298 K conditions. Online electrospray mass spectrometry (o-ESI- MS), which probes in situ the composition of the interfacial layers where ozonolysis takes place within 1 ms, was used to search for HMW (> C_{18}), α-acyloxyalkyl hydroperoxides from the addition of H_2O to CI, and other C_9 products. We explored the participation of water in these processes by performing experiments using D_2O and $H_2{}^{18}O$ instead of H_2O in the AN/W solvent. We found that HMW formation increases linearly both with O_3(g) exposure and OL concentration in the bulk solution, but decreases upon increasing the molar fraction of water. The main findings are that water functions as a solvent in the ionization of OL, and as a reactant that affects HMW formation.

2AC.4

There's No Place Like HOM: Modeling Peroxy Radical Chemistry to Understand HOM Yields. MEREDITH SCHERVISH, Wayne Chuang, Neil Donahue, *Carnegie Mellon University*

Knowledge of gas-phase oxidation chemistry is central to our understanding of aerosols. While gas-phase products of a wide range of volatilities are produced via oxidation of emitted precursors, low and extremely-low volatility gas-phase organic compounds are especially important because of their contribution to growth of particles as well as to the nucleation of new particles. Recent experimental work has shown the presence of highly oxidized molecules (HOMs), having vapor pressures in LVOC to ELVOC range, formed from the oxidation of alpha-pinene in both field and laboratory studies. These compounds are formed when peroxy radicals from the initial precursor oxidation "auto-oxidize" allowing them to rapidly undergo multi-generational oxidation chemistry. This process, involving a high energy barrier and thus being highly temperature-dependent, competes with radical termination reactions with NO_x, HO_2, and other RO_2 radicals. Under different conditions, this competition results in vastly different stable products. Under low NO_x and high temperature conditions, auto-oxidation dominates the fate of peroxy radicals leading to highly oxidized, low (and extremely low) volatility products including highly oxidized dimers. Under high NO_x and/or low temperature conditions, radical termination reactions dominate leading to products that are less oxidized and have higher volatilities. This competition is crucial in our understanding of the formation of ELVOC dimers as the dimer formation reaction may be dependent on the ability of RO_2 radicals to cluster together, requiring that they themselves have a low enough vapor pressure. This work seeks to underline the importance of the competition between auto-oxidation and radical termination under different conditions and explore HOM formation in chamber experiments through modeling.

2AC.5

Understanding the Fate of Highly Oxygenated Molecules in the Particle Phase Using an Extractive Electrospray Ionization Time-of-Flight Mass Spectrometer (EESI-TOF). VERONIKA POSPISILOVA, Felipe Lopez-Hilfiker, Claudia Mohr, Wei Huang, David Bell, Liine Heikkinen, Josef Dommen, Urs Baltensperger, Andre S.H. Prévôt, Jay G. Slowik, *Paul Scherrer Institute*

Atmospheric aerosols have significant impacts on human health and Earth´s climate. The highly oxygenated molecules (HOMs) yielded by the oxidation of biogenic and/or anthropogenic precursors contribute to the formation and growth of new particles in the atmosphere due to their low saturation vapor pressures. The molecular identification of these oxidized species in the gas phase is possible via chemical ionization mass spectrometry (CIMS) techniques. However, their identification and behavior in the particle phase remains an open question as currently no instrumentation allows online aerosol measurement on molecular level without thermal decomposition and/or ionization- induced fragmentation.

We present real-time measurements of individual organic aerosol species formed in alpha-pinene oxidation experiments in an atmospheric simulation chamber, as well as their direct observations in a boreal forest in southern Finland using a novel extractive electrospray ionization time-of-flight mass spectrometer (EESI-TOF) developed at PSI. We demonstrate that the EESI-TOF enables real time analysis of highly oxygenated molecules in the particle phase, without fragmentation, at atmospherically relevant mass loadings. We will present the separation of different generations of aerosol components and compare the results with measurements conducted by a FIGAERO-CIMS (Filter Inlet for Gases and AEROsols coupled to a CIMS), a well-established semi-continuous technique for aerosol composition measurement.

The analysis from these techniques makes it possible to investigate the evolution of these molecules in the particle phase and assess the degree of decomposition and/or accretion reactions occurring during the particle aging. Particle phase fragmentations reactions could be an important process that might reduce the overall efficiency at which low volatility gas phase organics contribute to the aerosol mass. It is also speculated that accretion reactions can lead to oligomerization in the particle phase, which could lead to a less volatile and, therefore, a more persistent form of secondary organic aerosol. Here, we will present evidence for particle-phase decomposition reactions.

2AC.6

The Role of Highly Oxygenated Molecules in Determining the Composition of Ambient Ions in the Boreal Forest.

FEDERICO BIANCHI, Olga Garmash, Xucheng He, Chao Yan, Siddharth Iyer, Matti Rissanen, Matthieu Riva, Nina Sarnela, Tuukka Petäjä, Douglas Worsnop, Markku Kulmala, Mikael Ehn, Heikki Junninen, Ida Rosendhal, Risto Taipale, Zhengning Xu, *University of Helsinki*

It has been recognized the ions can play a crucial role on atmospheric aerosol formation via the ion-induced nucleation mechanism. In order to investigate the negative ions in the boreal forest we have performed measurements to chemically characterise the composition of negatively charged clusters containing highly oxygenated molecules (HOMs). Additionally, we compared this information with the chemical composition of the neutral gas-phase molecules detected in the ambient atmosphere during the same period. The chemical composition of the ions was retrieved using an atmospheric pressure interface time-of-flight mass spectrometer (APi-TOF-MS) while the gas-phase neutral molecules (mainly sulfuric acid and HOMs) were characterised using the same mass spectrometer coupled to a nitrate-based chemical ionisation unit (CI-APi-TOF). Overall, we divided the identified HOMs in two classes: HOMs containing only carbon, hydrogen and oxygen and nitrogen-containing HOMs or organonitrates (ONs). During the day, among the ions, in addition to the well-known pure sulfuric acid clusters, we found a large number of HOMs clustered with nitrate (NO_3^-) or bisulfate (HSO_4^-), with the first one being more abundant. During the night, the distribution of ions, mainly composed of HOM clustered with NO_3^-, was very similar to the neutral compounds that are detected in the CI-APi-TOF as adducts with the artificially introduced primary ion (NO_3^-). For the first time, we identified several clusters containing up to 40 carbon atoms. These ions are formed by up to four oxidised-pinene units clustered with NO3-. While we know that dimers (16–20 carbon atoms) are probably formed by a covalent bond between two-pinene oxidised units, it is still unclear what bonding formed larger clusters. Finally, diurnal profiles of the negative ions were consistent with the neutral compounds revealing that ONs peak during the day while HOMs are more abundant at night-time. However, during the day, a large fraction of the negative charge is taken up by the pure sulfuric acid clusters causing differences between ambient ions and neutral compounds (i.e. less available charge for HOM and ON).

2AC.7

The Fate of Highly Oxygenated Organic Molecules in Wet Acidic Aerosols. LIINE HEIKKINEN, Matthieu Riva, Otso Peräkyla, Qiaozhi Zha, Simon Schallhart, Matti Rissanen, Tuukka Petäjä, Mikael Ehn, *University of Helsinki*

Organic aerosol (OA) makes up a large mass fraction of tropospheric fine particulate matter, worldwide. OA commonly originates from gas-to-particle transition processes and in this case can be referred to secondary organic aerosol (SOA). Biogenic volatile organic compounds (BVOCs) are an important source of SOA. Among the BVOCs, monoterpenes (MT) represent a major fraction of organic compounds produced over forested areas. In the boreal forest, α-pinene (AP) contributes significantly to the SOA formation through the generation of highly oxygenated molecules (HOMs). Indeed, such compounds are expected to have low vapor pressures and to significantly contribute to the formation of new particles in the atmosphere. In the presence of NO_x, the formation of multifunctional organic nitrates (ONs) has been reported as well as their subsequent presence in the particle phase. While the importance of HOMs and multifunctional ONs in SOA formation has been demonstrated, their fate within the particle phase has received much less attention and remain uncertain/unknown. It is worth noting that such compounds are expected to contain a wide variety of functional groups and thus are presumably highly reactive within the condensed phase.

In the present study, we investigated the fate of particulate HOMs both in the boreal forest in Southern Finland (SMEAR II station) and in a newly constructed atmospheric simulation chamber (COALA chamber). The laboratory experiments focused on the ozonolysis of AP under atmospherically relevant conditions. Seed aerosols with varying acidities and liquid water contents were used in order to replicate the conditions observed in the boreal forest. The particles sampled in both field and laboratory studies were chemically characterized utilizing different mass spectrometric techniques, such as a Filter Inlet for Gases and AEROsols coupled with an iodide adduct Chemical Ionization Mass Spectrometer (FIGAERO-CIMS) and a High Resolution Aerosol Mass Spectrometer (HR-AMS). Both instruments have an extended time-of-flight chamber enabling a high mass resolution and thus a more detailed understanding of the mass spectra. Our results from the field reveal that the HOMs, especially the dimers, undergo further particle phase reactions in the presence of sulfate aerosols, producing high molecular weight oligomeric products. These results were later confirmed by targeted laboratory experiments in the COALA chamber and stress the importance of acid-catalyzed reactions. Our study highlights that aerosol acidity leads to fast particle phase processing influencing the physicochemical properties of MT-derived SOA. Finally, the chamber studies reveal the decomposition of the particulate multifunctional ONs formed from the ozonolysis of AP in wet acidic aerosols, which could impact the atmospheric NO_x cycling.

2AC.8

Constraining the Abundance of Oligomers in Monoterpene Secondary Organic Aerosol. CHRISTOPHER KENSETH, Yuanlong Huang, Ran Zhao, Nathan Dalleska, Caleb Hethcox, Brian Stoltz, John Seinfeld, *California Institute of Technology*

High molecular weight oligomeric compounds have been identified as significant components of both ambient and laboratory-derived monoterpene secondary organic aerosol (SOA), and have been implicated as key players in new particle formation and growth, particle viscosity, and cloud condensation nuclei (CCN) activity. Electrospray ionization mass spectrometry (ESI-MS), typically coupled with liquid chromatographic (LC) separation, is among the most widely used analytical techniques for characterizing the identity and abundance of SOA molecular constituents. Due to a lack of authentic standards, oligomers in monoterpene SOA are typically quantified using commercially available terpenoic acids as surrogates (e.g., *cis*-pinonic acid and *cis*-pinic acid). However, due to fundamental differences in the ionizing behavior of monomers and oligomers, namely that oligomers produce ions with more delocalized charge, we have found through a combination of experimental and computational approaches that the sensitivity of ESI-MS toward oligomers is approximately two to ten times higher than that toward monomers, suggesting that the mass contribution of oligomers to monoterpene SOA has been significantly overestimated in past studies. In this work, we synthesize a series of monoterpene-derived oligomeric compounds and characterize their ESI efficiencies both empirically and theoretically. Using these oligomers as more representative surrogates, we constrain the abundance of oligomeric products in SOA derived from the O_3-initiated oxidation of α- and β-pinene, the most abundant monoterpenes in the atmosphere (total global emissions estimated at 85 Tg yr^{-1}). This critical analytical aspect of SOA formation experiments constitutes a potentially significant source of systematic bias in chamber-derived parameterizations of SOA production from monoterpene oxidation.

2AP.1

Observation of Nucleation Size Particles in the Amazon. FLORIAN DITAS, Christopher Pöhlker, Henrique Barbosa, Joel Brito, Samara Carbone, Xuguang Chi, Bruna A. Holanda, Isabella Hrabe de Angelis, Tobias Könemann, Jing Ming, Mira L. Pöhlker, Maria Prass, Daniel Moran-Zuloaga, Marta Sá, Jorge Saturno, Hang Su, Jian Wang, David Walter, Stefan Wolff, Alessandro Araujo, Paulo Artaxo, Ulrich Pöschl, Meinrat O. Andreae, *Max Planck Institute for Chemistry, Mainz, Germany*

New particle formation (NPF) and subsequent growth of nanometer particles is on a global scale responsible for a substantial fraction of the total particle budget and the number of cloud condensation nuclei (CCN). Under pristine conditions, the particle contribution by NPF can be of particular significance when the activation of CCN to cloud droplets is mostly limited by the amount of available aerosol particles.

One of the few continental places to study atmospheric aerosols under near-pristine conditions is the Amazon rainforest. Here, we will present observations from the *Amazon Tall Tower Observatory* (ATTO) site, which is located about 150 km northeast of the city of Manaus. The ATTO site is equipped to measure microphysical, chemical, hygroscopic and optical particle properties well-above (325 m), close to (60 m) and below (5 m) the canopy.

Particle number size distributions inside and above canopy suggest, at least, two different types of new particle formation events or sources. In contrast to the well-established continental banana-like events, a large fraction of the observed events at ATTO features a burst-like character without subsequent growth.

These events, which are typically shorter than 1-2 hours, occur more often during the dry season and sporadically in the presence of fog. The burst-like character and the sharp gradients of particle number concentration might indicate local particle sources.

In contrast, a more regional increase of nucleation size particles is frequently observed during the wet season and, in combination with vertical transport, often related to convective rainfall. In this study we investigate different event classes of nucleation size particles, their sources and significance vertically resolved inside, close to and well-above the Amazon rainforest canopy.

Investigation of Dependencies of the Condensation Behaviour on Automotive Exhaust Soot in Condensation Nuclei Counters. MARTIN KUPPER, Martin Kraft, Alexander Bergmann, *CTR Carinthian Tech Research, Villach, 9524, Austria*

Introduction: Condensation nuclei counters (CNC) are proven metrology devices for particle number (PN) concentration measurements, used in scientific, industrial and environmental applications alike and legally mandated for automotive exhaust characterisation. The condensation of the working fluid on the (nano)particles is known to depend on both, the particles and the working fluid. As presented already at the AAAR annual meeting 2017, the inherent potential of optimising and usefully exploiting fluid - particle matching remains largely untapped. Instead, n-butanol is presently used almost invariably for an undesignated mix of different aerosol particles. Similarly, condensation models assume spherical structures, neglecting the real, often highly complex surface structures of aerosol nanoparticles.

Methods: A correction model of the deviation in the effective CNC cutoff caused by the difference of a fractally shaped condensation nucleus to an ideal sphere was developed. This theory-based approach was backed by analysis of published counting efficiency curves using different nuclei and validated against this data. In a parallel effort, key factors describing particle species – working fluid interaction and resultant counting efficiency – have been compiled and are presently being experimentally examined using a dedicated research CNC with different working fluids and particle species and structures. To examine the dedicated influence of morphology on the nucleation process a study using small angle X-ray scattering (SAXS) on defined particles in a well-known CNC is in progress.

Results: Comparing the developed model with literature data indicates a strong dependency of nucleation efficiency on the respective material properties and furthermore a significant impact of the particle morphology. Both effects are hence significant for a correct determination of PN and a targeted further development of CNC-based aerosol analysers. Yet, the contributions of morphology and material matching to particle activation overlap and cannot be clearly and unambiguously separated experimentally. A test series was designed to settle this point by systematic examination of the nucleation on particles with different morphology but same material. By comparisons of the experimental results with the model, the correction of CNCs is further sharpened for measuring PN in automotive exhaust.

Quantifying Initial Nanoparticle Growth of Organic and Inorganic Systems with the CLOUD Experiment. DOMINIK STOLZENBURG, Lukas Fischer, Martin Heinritzi, Mario Simon, Katrianne Lehtipalo, Chao Yan, Lubna Dada, Paul M. Winkler, *University of Vienna*

New particle formation and subsequent nanoparticle growth has been identified as the main contributor to the global budget of cloud condensation nuclei (CCN), significantly impacting the Earth's radiative balance (Gordon et al. (2017), J. Geophys. Res.-Atmos., 122). In order to reach CCN sizes, high initial particle growth rates are crucial for the survival of freshly formed nanoparticles, at sizes below 10nm, as they rapidly coagulate with pre-existing aerosol. Characteristics of particle growth depend largely on the abundance of different condensable vapours and parameters such as temperature and relative humidity. Detailed studies exploring this wide parameter space are missing so far.

Here we present results from three measurement campaigns at the CERN CLOUD experiment (Duplissy et al. (2016) J. Geophys. Res. Atmos., 121, and references therein), exploring a wide range of parameters under precisely controlled conditions. Accurate quantification of sub-10 nm growth rates were achieved by using a DMA-train (Stolzenburg et al. (2017), Atmos. Meas. Tech., 10, 1639-1651) in combination with high-resolution mass spectrometry (Jokinen et al. (2012), Atmos. Chem. Phys., 12, 4117-4125; Breitenlechner et al. (2017), Anal. Chem., 89, 5824-5831).

Particle growth in several organic, inorganic and combined systems, including sulphuric acid, ammonia and highly oxidized molecules from alpha-pinene ozonolysis was measured in the temperature range between -50 and +25 °C. Moreover, experiments were performed for systems similar to those found in the atmosphere, by adding NOx and isoprene.

We find that the chemical system directly impacts the size-dependence of the growth rates and that especially the addition of NOx and isoprene influence the contribution of organics due to different resulting oxidation products. In this respect, also temperature plays a decisive role as volatility is the dominant parameter for the condensation of organic molecules. The resulting parametrization of growth rates with respect to condensable vapour concentrations will certainly help to improve the treatment of nanoparticle growth in global models. The insights gained into particle growth mechanisms by this set of experiments can possibly explain the occurrence of nanoparticle growth up to CCN sizes in various regions all over the globe.

2AP.4

Laboratory Study on the Impact of Organic Vapours on Water Uptake of Aerosols. DAWEI HU, David Topping, Gordon McFiggans, *University of Manchester*

Clouds have a profound influence on weather and climate. According to the Intergovernmental Panel on Climate Change (IPCC), the impacts of aerosols on clouds are one of the largest uncertainties in estimates of the global radiative forcing. The formation of cloud droplets by the condensation of water vapours on particles can be predicted by traditional Köhler theory, but this treatment is limited to involatile compounds with water vapour only and does not account for the influence of other inorganic or organic vapours. Previous modelling studies reported that co-condensation of inorganic or organic vapours on growing droplets could significantly enhance both cloud condensation nucleus (CCN) and cloud droplet number concentration, thereby influencing cloud albedo and climate. However, until now, there has been no direct observational evidence of this process.

Here, we use a modified Hygroscopic Tandem Differential Mobility Analyser (H-TDMA) system to investigate the growth of inorganic salt particles exposed to both water and organic vapours in the laboratory. The result shows that organic vapour plays an important role in water uptake process of aerosols consistent with our previous predictions. To our knowledge, this study reports the first direct measurement to quantify the influence of organic vapour on the water uptake of aerosols.

2AP.5

How Increased Ionization Can Boost Aerosol Growth to Cloud Condensation Nuclei. MARTIN BøDKER ENGHOFF, Henrik Svensmark, Nir Joseph Shaviv, Jacob Svensmark, *Technical University of Denmark*

In this study (Svensmark et al, 2017) the effect of ionization on the growth of aerosols into cloud condensation nuclei is investigated theoretically and experimentally. We show that the mass-flux of small ions can constitute an important addition to the growth caused by condensation of neutral molecules.

Under atmospheric conditions the growth from ions can constitute several percent of the neutral growth. We performed experimental studies which quantify the effect of ions on the growth of aerosols between nucleation and sizes up to 20 nm and find good agreement with theory. Ion-induced condensation could be of importance not just in Earth's present day atmosphere for the growth of aerosols into cloud condensation nuclei under pristine marine conditions, but also under elevated atmospheric ionization caused by increased supernova activity.

We propose an addition to the condensation equation based on the additional mass-flux of ions to aerosols. The expression depends on the ratio of the number concentration of ions to the number concentration of neutrals, the ratio of the interaction coefficient between ions and neutral aerosols to the interaction coefficient between neutral molecules and aerosols, the ratio of the ion mass to the neutral mass, and finally the ratio of the amount of neutral aerosols to the total amount of aerosols. While the second and fourth terms are (nearly) constant under most conditions the ion/neutral number concentrations and mass vary depending on atmospheric conditions. In a pristine environment at high ionization levels the effect can account for almost 20% of the growth rate of small aerosols and a significant enhancement up to 20-30 nm.

The theory was tested experimentally in 7 m^3 atmospheric reaction chamber, measuring the aerosol size distribution and (for some of the experiments) the sulphuric acid concentration. A total of 3100 hours of data with varying gas and ion concentrations were analyzed. For each set of experimental conditions a number of experiments where ionizing gamma sources were opened and closed with typically 2 hour intervals were performed. We then superposed the individual experiments onto each other to reveal the growth profile with and without increased ionization. Analyzing these superposed growth profiles allowed us to compare growth rates with and without ionization to the theory and we found a good agreement between the two.

The mechanism is favoured by high ionization, low gas concentrations, and low aerosol concentrations. This points to pristine settings, such as over oceans away from continental and polluted areas. Potentially the mechanism can contribute significantly to the production of cloud condensation nuclei, but to fully assess the impact the mechanism should be included in global climate simulations.

2AP.6

Ageing of Sea Spray Aerosols: Effects on Hygroscopicity and Cloud Droplet Activation. BERNADETTE ROSATI, Sigurd Christiansen, Robert Lange, Andreas Massling, Merete Bilde, *Aarhus University*

Sea spray aerosols (SSA) are continuously emitted into the Earth's atmosphere and play a significant role in the planetary energy budget, by interacting directly with solar radiation and by affecting the formation and lifetime of clouds. This has a major effect on climate since 70% of the planet is covered by the ocean, which thereby is the largest single source of aerosol mass in the atmosphere (e.g. de Leeuw et al. 2011). The atmospheric lifetime of SSA varies from seconds to weeks. During this time, SSA is exposed to oxidants, condensable vapors, light and changing conditions of relative humidity and temperature, which induce so-called ageing effects. Hence, the properties of SSA may be significantly altered, which leads to changes in their role for climate.

The hygroscopic behavior of SSA, at sub- saturated conditions of relative humidities (RH), influences the type and magnitude of the aerosol-radiation interactions because the optical properties of the aerosol particles change due to water uptake. The hygroscopicity may also affect the particles' efficiency to act as cloud condensation nuclei (CCN) at supersaturated conditions. Commonly, the hygroscopicity and CCN-activity of SSA is assumed to be comparable to that of sodium chloride (NaCl; Lewis and Schwartz, 2004), which is the major component of SSA particles overall (Lewis and Schwartz, 2004). Previous laboratory studies have investigated reactions of aqueous NaCl with ozone and the presence of UV-light, hereby mimicking ageing conditions occurring in the marine boundary layer (Knipping et al., 2000, Laskin et al., 2003). These experiments demonstrated changes in the chemical and physical properties of the particles and hence the authors hypothesize a possible effect on the hygroscopic and cloud activation potential.

In this study, we examine the hygroscopic and cloud forming potential of SSA after atmospheric ageing processes. To simulate different atmospheric conditions, we use the constrained conditions of the Aarhus University Research on Aerosol (AURA) smog chamber (Kristensen et al., 2017), which provides a temperature regulation between 257 and 299 K. In our experiments, the chemical composition of SSA is first simplified by using pure NaCl particles generated with a TSI atomizer. In a second step, another generation technique, i.e. a sea spray chamber, and more complex mixtures of inorganic salts are used. Hygroscopicity is measured with a humidified tandem differential mobility analyzer (Brechtel) while a cloud condensation nucleus counter (DMT) is used to investigate the cloud droplet activation of the fresh and aged particles. Additionally, the particle number size distribution is monitored with a scanning mobility particle sizer (SMPS; TSI) and an optical particle sizer (OPS; TSI). We will present first results of ageing experiments, where NaCl undergoes oxidation due to gases and UV-radiation as present in the atmosphere. We will show that only deliquesced NaCl particles lead to chemical reactions influencing the hygroscopic and CCN-activity and that the results strongly depend on the pre-treatment of the aerosol particles.

2AP.7

A Unifying Identity for the Work of Cluster Formation in Heterogeneous and Homogeneous Nucleation Theory.

ROBERT MCGRAW, Paul M. Winkler, Paul E. Wagner, *Brookhaven National Laboratory*

Nucleation in the atmosphere is responsible for the formation of new particles that can subsequently grow to exert a significant impact on global climate directly through the scattering and absorption of solar radiation and indirectly by serving as sites for cloud droplet condensation. There is evidence that both homogeneous nucleation and heterogeneous nucleation pathways contribute to this process. Indeed, the interesting two-stage model of Kulmala and co-workers: heterogeneous nucleation of (most likely) oxidized organic vapors on stabilized 1-2 nm neutral cluster condensation sites formed from the gas phase, effectively eliminates distinction between heterogeneous and homogeneous nucleation mechanisms as the condensation sites approach molecular size. A unifying identity is derived in the present study relating the surface and volume components of the reversible work of cluster formation. Shown to generalize two early thermodynamic relationships of Gibbs, the new result is demonstrated here for Fletcher's model of heterogeneous nucleation on flat and curved substrates and in the homogeneous nucleation limit, for clusters of non-critical as well as critical size, and for application to non-classical (molecular-based) theories. The new identity can serve as a check on the consistency of complicated theoretical expressions and numerical calculations and help guide interpretation of measurements.

2AP.8

Controlling and Explaining the Formation of Bimodal Aerosol Distributions in Laboratory Studies. Phoebe Belser, Hemanta Timsina, Dabrina Dutcher, TIM RAYMOND, *Bucknell University*

Because of the abundance of dicarboxylic acids in the atmosphere, they are commonly studied in the aerosol field, specifically investigating their hygroscopic and cloud condensation nuclei activity properties along with their behavior in inorganic mixtures. Glutaric acid, being a water soluble dicarboxylic acid is commonly used to model water activity in dicarboxylic acid aerosols. Studying trends associated with glutaric acid aerosols in the atmosphere, such as CCN activity and water uptake behavior is common. Glutaric acids behavior in the presence of inorganic particles, such as coating inorganic aerosols and forming co-crystals, is also frequently studied. However, in several circumstances there is some variability within the data associated with glutaric acid, specifically DRH and hygroscopic data, which is hypothesized to be caused by its polymorphism.

Glutaric acid exhibits dimorphism, meaning the molecule can form into two different types of crystal structures, an alpha and a beta polymorph, which can manefest themselves as a bimodal aerosol size distribution when analyzed by SMPS or other mobility sizing methods. Glutaric acid naturally forms in the beta polymorph, which is more stable. The alpha polymorph is the metastable phase, meaning it is less stable. In this work we investigated the formation of the alpha glutaric acid polymorph in aerosols generated from an aqueous glutaric acid solution. In no published research has the formation of both polymorphs from an aqueous solution been documented. Identifying the presence of polymorphism in glutaric acid aerosols will ideally explain the variability present in studies associated with glutaric acid aerosols. Understanding and defining under which conditions the alpha polymorph is present will allow others to avoid it when investigating glutaric acid as a dicarboxylic acid.

Additionally, bimodal distributions have been observed with select mixtures of organic and inorganic substances, however the mechanism creating biomodality appears to be different than polymorphism. These results will be presented and explained.

2CA.1

Understanding the Physical and Optical Properties of Black Carbon Aerosols at Delhi and Kanpur in Indo-Gangetic Plain. NAVANEETH M. THAMBAN, S.N. Tripathi, Shamjad P.M., *IIT Kanpur*

The mass concentration, size distribution, and absorption properties of black carbon (BC) aerosols were measured at two different sites in the Indo-Gangetic Plain (IGP) for improving the radiative forcing calculations. A Single Particle Soot Photometer (SP2) and Photo Acoustic Soot Spectrometer (PASS-1) were operated at Kanpur and Delhi for the year of 2015 and 2018 respectively during the winter season. The mean mass absorption cross-section values (MAC_{781}) for Delhi was slightly higher than that of Kanpur (11.04 m^2/g, 10.1 m^2/g respectively) during the sampling period. The relative lower mode BC number size distribution at Delhi suggested the presence of nearby BC sources in Delhi than Kanpur. In addition, the higher variability in the BC number to mass ratio indicates the heterogeneity in the BC sources in Delhi than Kanpur.

2CA.2

Influences of Primary Emission and Secondary Coating Formation on the Mixing State of Black Carbon-containing Particles.

ALEX LEE, Chia-Li Chen, Jun Liu, Derek Price, Raghu Betha, Lynn Russell, Xiaolu Zhang, Christopher Cappa, *National University of Singapore*

Black carbon (BC) emitted from incomplete combustion can result in significant impacts on air quality and climate. Understanding the mixing state of ambient BC and the chemical characteristics of its associated coatings is particularly important to evaluate BC fate and environmental impacts. In this study, we investigate formation of coating on BC particles and aerosol mixing state near traffic emissions under hot and dry conditions in Fontana, California using an Aerodyne soot-particle aerosol mass spectrometer (SP-AMS). The SP-AMS was operated in a configuration that can exclusively detect refractory BC (rBC) particles and their non-refractory coating materials, including organic, nitrate, sulfate, ammonium and chloride.

Substantial formation of secondary organic aerosol (SOA) coatings on rBC particles was observed due to active photochemistry in the afternoon, whereas primary organic aerosol (POA) components were strongly associated with rBC from fresh vehicular emissions in the morning rush hours. Nitrate peaks were observed in the late morning due to formation of nitric acid via OH radical oxidation of NO2 in traffic emissions. Using the −log(NOx ⁄ NOy) ratio as a proxy for photochemical age of air masses, most of the observed SOA coatings were freshly formed, providing an opportunity to examine SOA coating formation on rBCs near vehicular emissions. Comparison of our results to a co-located standard high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) measurement suggests that approximately 7–20 wt % of secondary organic and inorganic species were estimated to be internally mixed with rBC on average, implying that rBC is unlikely the major condensation sink of secondary species.

Event Trigger mode of SP-AMS was used to measure chemical composition of individual rBC-containing particle. Preliminary results of cluster analysis of single-particle measurements indicate the presence of various types of primary and secondary coatings based on their mass spectral characteristics. The mixing state index, χ, was calculated for quantifying the degree of mixing of rBC and coating materials (i.e., χ = 0 and 1 means that all particles are fully externally and internally mixed, respectively). The mixing state index varied between 0.2 and 0.6 with the average of 0.38 (± 0.06) in this study, and was not sensitive to the photochemical age of air masses. Nevertheless, the average particle species diversity (D_α) and the bulk population species diversity (D_γ), which represent the average effective number of species in each particle and the effective number of species in the population, respectively, slightly increased with primary traffic emissions and/or nitrate formation but gradually decreased with SOA formation during the afternoon. These observations indicate that substantial SOA formation observed in the afternoon led to more homogeneous particle compositions.

2CA.3

Black Carbon Aerosol in a Clean Marine Environment. WALT WILLIAMS, Armin Sorooshian, Haflidi Jonsson, Richard Flagan, John Seinfeld, Andrew Metcalf, *Clemson University*

Black carbon (BC) aerosol was measured with a Single Particle Soot Photometer (SP2) in a relatively clean, marine environment in the Eastern Pacific, just off the central coast of California. In this region, direct emission of BC aerosol comes mostly from the shipping industry, with occasional inputs from biomass burning in California (although most emissions over land are carried eastward across the continental United States). Some BC aerosol in the region is from long-range transport from Asia. Regardless of BC source, the mixing state of individual BC aerosol particles can have a large effect on its climate-forcing potential and lifetime in the atmosphere. Recent results from other studies in remote marine environments show that some regions are characterized by uncoated BC, while other regions have nearly all BC aerosol mixed with water-soluble materials.

In this talk, measurements of BC mass, size distribution, concentration, and mixing state will be presented for a clean marine environment from 2 sampling campaigns: from summer of 2011 and summer of 2018. BC aerosol measurements will be compared to other measurements of total aerosol size, concentration, and chemical composition. One goal of this study is to use the BC mixing state information from the SP2 measurements to identify new emission sources of BC aerosol versus BC from long-range transport. To accomplish this goal, measurements from near-ship will be compared to those above the boundary layer to identify plume profiles from different aerosol sources. Another goal of this study to examine BC characteristics in droplet residual particles in relation to other inorganic and organic constituents. To accomplish this goal, some sampling periods were behind a counterflow virtual impactor. Finally, characteristics of long-term trends in BC aerosol in this region will be inferred from a comparison of these sampling campaigns 7 years apart.

2CA.4

Quantifying Black Carbon Light Absorption Enhancement with a Novel Statistical Approach. Cheng Wu, Dui Wu, JIAN ZHEN YU, *Jinan University*

Black carbon (BC) particles in the atmosphere can absorb more light when coated by non-absorbing or weakly absorbing materials during atmospheric aging, due to the lensing effect. In this study, the light absorption enhancement factor, E_{abs}, was quantified using a 1-year measurement of mass absorption efficiency (MAE) in the Pearl River Delta region (PRD). A new approach for calculating primary MAE (MAE_p), the key for E_{abs} estimation, is demonstrated using the minimum R squared (MRS) method, exploring the inherent source independency between BC and its coating materials. A unique feature of E_{abs} estimation with the MRS approach is its insensitivity to systematic biases in elemental carbon (EC) and σ_{abs} measurements. The annual average E_{abs550} is found to be 1:50±0:48 (1 SD) in the PRD region, exhibiting a clear seasonal pattern with higher values in summer and lower in winter. Elevated E_{abs} in the summertime is likely associated with aged air masses, predominantly of marine origin, along with long-range transport of biomass-burning-influenced air masses from Southeast Asia. Core– shell Mie simulations along with measured E_{abs} and absorption Ångström exponent (AAE) constraints suggest that in the PRD, the coating materials are unlikely to be dominated by brown carbon and the coating thickness is higher in the rainy season than in the dry season.

2CA.5

Impact of Diesel Container Truck Emissions on Carbonaceous Aerosols in a Unique Roadside Environment in Hong Kong.

YEE KA WONG, Jian Zhen Yu, *Hong Kong University of Science and Technology*

Street-level air pollution is a major concern in Hong Kong, and over the years the Government has implemented a series of measures to reduce the vehicular emissions, particularly those from diesel commercial vehicles. This work demonstrates multiple approaches in estimating vehicular contribution to $PM_{2.5}$, which potentially serves as the basis for evaluating the ongoing vehicle emissions control policies. A Sunset Laboratory semi-continuous OC-EC field analyzer was deployed to measure the hourly concentrations of $PM_{2.5}$ organic carbon (OC) and elemental carbon (EC) at Lok Ma Chau Control Point (LMC), an ad hoc roadside site in Hong Kong, in 9 selected months from 2015 to 2017. The site is located in an open area near the boundary between Hong Kong and Mainland China, and is characterized as being heavily impacted by the exhaust from diesel container trucks passing by en route to Mainland China. The monthly average (± standard deviation) OC ranged from 2.89 ± 1.94 to 7.10 ± 3.41 μgC/m^3, with a higher contribution in winter mainly due to regional transport. EC ranged between 1.98 ± 1.24 and 4.01 ± 1.70 μgC/m^3, and is found strongly associated with diesel goods vehicle number when diurnal and weekday-holiday patterns were investigated. A very low traffic volume period during Chinese New Year (CNY) holiday was also captured, during which the rush hour EC plummeted to 1.13 ± 0.38 μgC/m^3, compared to 3.93 ± 1.43 μgC/m^3 outside the CNY period. The multiple pieces of evidence further corroborate EC as the effective tracer for diesel vehicular exhaust. In view of this and the roadside characteristics of the sampling site, $PM_{2.5}$ from vehicular exhaust (PM_{veh}), equivalent to the sum of EC and vehicle-related organic matter, was estimated through EC-tracer method. The OC-to-EC ratio of vehicular exhaust was determined to be 0.53 based on the optimal Deming regression using the lowest 5% data by OC/EC ratio from summer. The distribution of the selected data aligned well with the diurnal traffic volume pattern. On a monthly basis, the PM_{veh} were between 3.45 ± 2.17 and 6.99 ± 2.96 μg/m^3. PM_{veh} was also estimated independently by positive matrix factorization (PMF) considering major species and organic tracers (including hopanes) derived from 24-hr filter-based measurements at the same roadside site and one nearby general site. The results are tightly consistent with each other. For the overlapping samples the ratio in PM_{veh} between the two approaches is 1.04 ± 0.45, while that for vehicular OC is 0.89 ± 0.39 ($n = 22$), adding credence to the two approaches in providing estimation of PM_{veh}. Based on the PMF results, the vehicular exhaust was responsible for 14.6% of $PM_{2.5}$ and 19.3% of OC at LMC site.

2CA.6

Development of Size-resolved Black Carbon Particle Number Emission Inventory for Global Civil Aviation. XIAOLE ZHANG, Xi Chen, Jing Wang, *ETH Zuerich*

The air traffic is growing rapidly. The black carbon (BC) in the aviation exhaust may impact climate, environment and public health. The particle number and size distribution are relevant metrics for toxicological analysis and aerosol-cloud interactions.

In this study, a size-resolved BC particle number emission inventory is developed for the global civil aviation based on the recent measurements. The development follows the European Environment Agency (EEA) air pollutant emission inventory guidebook by utilizing the global scheduled flight dataset in 2005. The BC mass emission indices for nearly 300 types of aircrafts under various flight conditions are also provided by EEA. The mass-number conversion is conducted using fractal aggregate theory and the particle mass parameters obtained from experiments. The geometric mean diameters (GMD) and geometric standard deviations (GSD) of the particles are estimated with a new correlation based on the combustor inlet temperature (T_3) and BC mass emission index (EI_m) of the aircraft engines. Other flight parameters (e.g. speed, altitude, duration) are defined based on the statistics of thousands of Automatic Dependent Surveillance-Broadcast (ADS-B) and Flight Data Recorder (black box) records.

The number of civil aviation emitted BC particles is estimated to be 1.09×10^{26} per year (with 95% prediction interval of $6.8\sim15.0\times10^{25}$ per year) and the mass emission 9.5 Gg per year. The LTO cycles below 3000 ft (taxi, take-off, climb-out, and approach) and CCD (climb, cruise, and descent) above 3000 ft respectively account for 10.2% and 89.8% of the total particle number. The global mean BC GMD is the largest in take-off, then climb out, climb and cruise. The approach, taxi, and descent phases have the lowest GMDs. The global mean GSDs of different phases are all comparable, within a narrow interval between 1.80 and 1.85. The results indicate that the civil aviation has a much higher contribution to the total anthropogenic particle number emission than that to the mass emission.

Significant spatial heterogeneity has been observed. The number and mass emissions in Asian, Europe, America and other markets are related to the air traffic volume but subjected to modulation by the airplane type. The number emission index varies from about 5.5×10^{14} per kg-fuel in Northern America to 1.2×10^{15} per kg-fuel in C.W. OF IND. STATES due to the significant spatial variations in GMDs (about 29 nm in Northern America and 38 nm in C.W. OF IND. STATES.), which is mainly caused by the different dominant airplane types.

The developed emission inventory can be used as input data for air quality/climate models. The uncertainties in the inventory need further investigation.

2CA.7

Physico-chemical Characterization of Small-scale Gas Flaring. Alberto Baldelli, Ramin Dastanpour, Una Trivanovic, Melina Jefferson, Jason S. Olfert, Alireza Moallemi, Kevin Thomson, Matthew Johnson, Olga Popovicheva, STEVEN ROGAK, *University of British Columbia*

The properties of particulate emissions affect their impact on the environment and the human health. Flaring operations in the oil and gas industries can be major sources of soot, but are presently not well characterized. Carleton University has a laboratory flame that approaches the scale of a small industrial flare. This facility was used to study emissions relevant to flaring in Canadian oil and gas production. Three fuel compositions (mixtures of methane, ethane, propane, butane, N2, and CO2), a range of exit velocities (0.5 to 1.5 m/s), and burner diameters of 38, 51, and 76 mm were studied.

A broad suite of optical, physical, and chemical characterization techniques was used to allow a comprehensive characterization of the gas flare particulate emissions. Individual particles were analyzed using High Resolution Transmission Electron Microscopy (HRTEM), Raman Spectroscopy, and Scanning Electron Microscopy coupled by Energy Dispersive X-ray (SEM-EDX) spectroscopy. Furthermore, a Fourier transform infrared (FTIR) was used on bulk samples of soot for a deeper analysis of its chemical structure. The major type is soot distinguished by agglomerates of ultrafine primary particles of 30 ± 10 nm diameter containing from a few up to hundreds of spheres. HRTEM images are characterized by the length, tortuosity and separation of individual graphene fringes in soot. Analysis of Raman spectroscopy is sensitive to the degree of graphitization and crystal sizes in disordered carbon. We found here that Raman spectra were very similar for soot from all fuels considered. From EDX we found that as expected, every particle was composed mainly of C and O. Cluster analyses of composition data proposes the separation of into characteristic groups representative of various gaseous fuel mixtures and operation conditions. Group “Elemental Carbon” accounts for 86 to 97% of particles while Group “Oxidized Soot”, which are for the 70% made of oxygen, appeared with abundance of a few percent.

Characterization of bulk composition by thermo-optical transmission (TOT) method using a semi-continuous OC/EC analyzer with organic vapour trap, showed the particulate to have a very high elemental to total carbon (EC/TC) ratio across all flare test points. For the organic fraction, FTIR spectra shows the major classes of organic compounds determined by aliphatic C-C-H, aromatic C=C, and carbonyl C=O functionalities.

2CA.8

Inter-Comparison of Techniques for the Measurement of Black Carbon from Biomass Burning: Influence of Optical and Chemical Properties. HANYANG LI, Kara D. Lamb, Joshua P. Schwarz, Vanessa Selimovic, Robert J. Yokelson, Gavin McMeeking, Andrew May, *The Ohio State University*

Biomass burning is a major contributor to global black carbon (BC) emissions. However, the exact magnitude of BC emissions from biomass burning is difficult to examine due in part to highly variable combustion conditions and irregular spatiotemporal repeatability (e.g., wildfire emissions do not follow a regular weekly pattern throughout the year). An additional complication is that there are many approaches that can be used to measure BC emissions. Predominant methods in use today represent one of three distinct operationally-defined quantities: “equivalent” BC (eBC), “refractory” BC (rBC), and elemental carbon (EC). Given that EC might be used to represent eBC or rBC, and vice versa, it is essential to understand the relationship among BC measurements, and develop robust BC emission factors for biomass burning.

To systematically assess BC measurement techniques and investigate the uncertainties of BC emissions from biomass burning, we participated in the Fire Sciences Laboratory studies in Missoula, MT during Autumn 2016 as part of the Fire Influence on Regional and Global Environments Experiment (FIREX). Eight real-time instruments were deployed sharing the same smoke inlet, including two in situ methods for eBC, five filter-based methods for eBC, and one method for rBC; furthermore, quartz filters were collected for off-line thermal-optical analysis of EC. There have been similar prior efforts, but none that focused on biomass burning smoke have been this comprehensive (and none have compared EC and rBC). This presentation extends our previous work to compare EC with light-absorption measurements of BC. Quartz and quartz-behind-Teflon® filter samples containing EC and OC are analyzed using Sunset Laboratory OCEC analyzer by IMPROVE-A temperature protocol. Such filter data is also used to calculate organic aerosol concentration (C_{OA}), bare-quartz organic mass (OM) and particle-phase organic mass fraction (X_P), and thus we can evaluate the effect of OA gas-particle partitioning on emission factors of BC.

In our presentation, the association between BC uncertainties and intercorrelated optical and chemical properties of biomass burning (e.g. single scattering albedo, angstrom absorption exponent, absorption enhancement, C_{OA}, and OC/EC ratio) will be illustrated using both statistical methods and an alternative graphical/parametric approach. Our results indicate that both fixed and proportional biases are present among instruments. Fixed biases exist when comparing three general BC techniques (as well as various instruments using the same measurement technique). Measurements of BC may be also biased either high or low depending on aerosol properties and OA gas-particle partitioning, which is classified as proportional biases. This work will encourage accurate quantification of BC emissions from biomass burning and improve the predictions of climate and chemical-transport models.

An Integrated Modeling and Optimized Operating Method for Electrostatic Precipitation Process of Particulate Matters. YISHAN GUO, Yueqi Huang, Chenghang Zheng, Weiguo Weng, Yi Wang, Xiang Gao, *Zhejiang University, China*

Electrostatic precipitators (ESPs), widely utilized as the main particulate matter(PM) removal facility in flue gas treatment system of coal fired power plants, are high power consuming facilities consisting dozens of high voltage power supplies. Existing operating methods, lacking the comprehensive understanding of PM removal process and its relationship with energy consumption, could not fully cultivate the energy saving potential, and the feedback methods for operation voltage was unable to maintain a reliable outlet concentration. In this article, an integrated model, considering both precipitation mechanism of particulate matters together with the energy consumption, was put forward to monitor the operation of ESPs under varying operation parameters. The charging, migration and removal behavior of particulate matters under different energy injection level in wire-duct ESPs was comprehensively studied and the model to predict the outlet concentration was corrected through real operation data. At the same time, the emission distortion introduced by load shifting, flow distribution, ramping, etc., was analyzed. Based on the integrated model, coordinated operation set points for multiple cascaded and parallel discharging fields were achieved utilizing optimized operating method. In order to ensure the compliance rate of outlet concentration, a unique emission preferential method, which modifies the corrections of operation set points according to the optimized value together with the real time emission, was created and the optimized set points were compared with the real time operating point to get the correction gain and modify the operation set point to meet the emission goal. The method was adopted at an industrial ESP and a 100% of hourly compliance rate with more than 30% energy consumption reduction was achieved.

Pollutant Emissions from Steelworks Equipped with Various Flue Gas Desulfurization Systems. QING LI, Di Wu, Xiang Ding, Xianmang Xu, JianMin Chen, *Fudan University*

China has been the largest steel producer since 1997, and has accounted for about a half of the total world steel production since 2013. Pollutant emissions from sintering machines of steelworks is one of the largest contributor to China’s PM2.5 pollution. Compared to the great efforts made to limit emissions from coal-fired power plants, the percentage of air pollution control devices installed in steelworks is much lower, e.g. flue gas desulphurization systems (FGD) are used in less than 40% of the steelworks. This is due to less public concern and very complex flue gas composition, which has challenged the current FGD technologies.

This study compares removal efficiencies of various pollutants by using active coke, ammonia, and limestone FGD systems based on field measurements. The three FGD systems were installed to clean flue gases for three typical sintering machines, all of which used the same combustion technologies and fuels. The capacity of sintering machine equipped with the dry FGD system (active coke) is 600 m2, while that of the other two wet FGD system (ammonia and limestone) are both 360 m2. Wet electrostatic precipitators were installed for both wet FGD systems. It was found that the efficiency to remove SO2 was sufficient for all the three FGD technologies (>98%). However, compared to the other systems the ammonia FGD is less efficient in removing SO3, which may contribute to primary particulate matter in the flue plumes. Moreover high concentrations of ammonia (2021 mg/ m3) were observed in the flue plume after the ammonia FGD. These high ammonia concentrations are probably caused by carryover from the ammonia FGD system, and should be addressed in the future. Furthermore, compared to the other systems a higher concentration of soluble ions after ammonia FGD was detected owing to the lower removal efficiency of SO3 and slip of ammonia from the FGD system. Comparing dust concentrations at FGD inlets and outlets, the dust concentration in ammonia and limestone FGD outlets were decreased by 61% and 50%, respectively, while that at the active coke FGD outlet was increased by 5%.

To conclude, although all three FGD technologies are effective in removing SO2, the high rate of ammonia slip from ammonia FGD system should be considered, as well as its low efficiency in removing SO2. According to our results we recommend the limestone FGD technology for cleaning flue gases from sintering machines in steelworks.

2CM.3

Sampling Efficiency of PM10 Inlets with Different Impaction Substrates. THI-CUC LE, Krishna Kumar Shukla, Jung-Che Sung, Jia Feng, Ziyi Li, Chuen-Jinn Tsai, *National Chiao Tung University*

The EPA louvered PM10 inlet (16.7 L/min) is commonly used in PM10 FRM samplers or FEM monitors. The particle collection efficiency of the PM10 inlet is influenced by the wind speed, particle bounce and particle overloading. To study the effect of wind speeds, the sampling efficiency of PM10 inlet was calculated as the product of the particle collection efficiency of the PM10 impactor determined in our laboratory with the sampling effectiveness of TSP inlet at different wind speeds (Vanderpool et al., 2018). The test results of the particle collection efficiency of the impactor showed the cut-size of 10.29 ± 0.07 µm and sharpness of 1.37 ± 0.03, which are very close to those determined from the sampling efficiency of the PM10 inlet at different wind speeds. The estimated bias in PM10 concentrations at different wind speeds (2, 8, and 24 km/hr) is less than 3.1%, 6.7% and 13.8% as compared to USEPA's ideal concentrations, and less than -4.9%, -2.8 and 10.4 % as compared to the concentrations calculated by Tolocka et al. (2001), respectively. That is, the measured PM10 is influenced by the wind speed, especially when the wind speed is high. To study the effect of particle overloading, four clean PM10 inlets with grease-coated impaction surface were tested for 5 days sampling. The results showed good comparability ($R^2 > 0.97$) among four inlets. However, the field comparison test of cleaned and uncleaned (not clean daily) PM10 inlets showed that the uncleaned PM10 inlet oversampled PM10 after the first 3-day sampling since particles bounce off from the multiple layers of collected particles on the impaction substrate.

In this research, an oil-soaked glass fiber filter (GFF) supported by an oil-soaked 25-mm porous metal disc was used to replace the grease-coated flat impaction surface of the PM10 impactor to eliminate particle bounce. The laboratory test results showed that the modified PM10 impactor had the same cut-size and sharpness as the original PM10 impactor. The field comparison test of the modified PM10 inlet collocated with cleaned and uncleaned original PM10 inlet is being conducted at National Chiao Tung University, Taiwan. The modified PM10 inlet is expected to eliminate particle overloading during longer sampling period since silicone oil will wick up through the layers of collected particles to reduce particle bounce.

Keywords: PM10, aerosol sampling, particle bounce, particle overloading

Performance of Compact Cyclones with Taper-Shaped Bodies. PENG WANG, Di Liu, Da-Ren Chen, *Virginia Commonwealth University*

Cyclones have been widely used in a variety of industrial sectors for either removing or recovering particulate matter (PM). It is because of the low cost of machining, operation and maintenance of cyclones. Extended researches have been performed to investigate the performance of cyclones in various geometrical designs. This study introduces a new type of cyclones whose bodies are tapered instead of straight in conventional cyclones. The performance of cyclones with three different contraction angles of 0°, 30° and 60° were experimentally evaluated to study the effect of contraction angle on the cyclone performance. Two experimental setups were used to measure the penetration of particles through the studied cyclones. Polydisperse KCl particles were generated in both experimental setups. In one setup, the large particle aerosol generator (TSI 8180) was used to generate supermicrometer particles, and the optical particle spectrometer (OPS TSI 3330) was applied to measure the particle size distributions both upstream and downstream of studied cyclones. A make-up flow line (with HEPA filter and flow controller) was also included in the setup to vary the cyclone flow rates. In the other setup, a custom-made Collison atomizer was utilized to generate submicrometer particles, and the scanning mobility particle sizer (TSI 3096) was used to measure the particle size distributions both upstream and downstream of studied cyclones.

Our study shows that, the cut-off particle size for each taper-shaped cyclone decreased with the increase of cyclone flow rates. Under the same cyclone flow rate, the cut-off size would decrease with the increase of contract angles. For instance, at the cyclone flow rate of 2 L/min, the cut-off particle size for the cyclone with the 60°-taper-shaped body is ~ 1.7 µm with the pressure drop of 2.26 inH2O, while for the cyclone whose contraction angle is 0°, the cut-off size is ~ 2.6 µm with a pressure drop of 2.14 inH2O. The linear correlation between the dimensionless cutoff particle size and annual flow Reynolds number for studied cyclones was further found in this cyclone study. The regression of the linear correlation could be useful in the future design of cyclones with taper-shaped bodies.

The pressure drop of cyclones at different operational flow rates was also characterized. It is found that the cyclone pressure drop increases quadratically with the operational flow rate for all the studied cyclones. At the same flow rate, the 60°-taper-shaped cyclone has the highest pressure drop and the 0°-taper-shaped cyclone has the lowest drop. On the other hand, it is observed that, among three studied cyclones, the pressure drop of the 60°-taper-shaped cyclone is the lowest for the same cut-off particle size. The above finding implies that cyclones with taper-shaped bodies can effectively remove particles at the lower operational flow rate. Consequently, cyclones with tapered-shaped bodies can save more energy than conventional ones. Because of their compact design, studied cyclones can also be applied as the size-selective inlets for miniature aerosol sensors.

Application of Wet Phase Transition Agglomerator for Synergistic Removal of Fine Particles and Sulfur Trioxide from Stationary Source Flue Gas. Houzhang Tan, Ruijie Cao, Renhui Ruan, Shengjie Bai, XUEBIN WANG, Yongle Du, Hexin Liu, *Xi'an Jiaotong University, China*

A novel technology termed Wet Phase Transition Agglomerator (WPTA) was developed, based on particle growth and agglomeration by heterogeneous condensation, Brownian diffusion, thermophoresis, diffusiophoresis and disturbed pipe flow. The further removal of fine particles and SO_3 from flue gases downstream the wet flue gas desulfurization (WFGD) can be realized by the WPTA in coal-fired power plants.

The WPTA was commercially applied at a 100 MW coal-fired power station unit independently for the first time, after the lab- and pilot-scale experiments and industrial trial cooperating with a wet electrostatic precipitator. It was installed between the WFGD and chimney, and field measurements were conducted to evaluate its performance. The results indicated that the ultra-low emission of particle was realized by the WPTA, and it performed well on SO_3 removal.

The removal efficiency of particles were 53.05% and 71.11%, respectively, at the boiler loads of 90% and 75%. The particle emission was kept below 3 mg/m^3 by the WPTA. Although the concentration of SO_3 was relatively low at the outlet of WFGD due to wet scrubbing, the WPTA could further remove the SO_3 from flue gases. The removal efficiency of SO_3 were 19.29% and 18.87%, respectively, at the boiler loads of 90% and 75%. The SO_3 emission was kept below 2.5 mg/m^3 under all measurement conditions.

Keywords: fine particle; SO_3; growth; agglomeration; simultaneous removal

2CM.6

Evaluation of Particle Loading Performance of Two-stage Filtration System. XINJIAO TIAN, Qisheng Ou, David Y. H. Pui, *University of Minnesota*

Intake air filters are widely used in many industrial sectors to migrate the particles emissions, however, its resistance often increases rapidly and dust holding capacity is low. Installing a pre-filter before the main stage intake air filter is an effective way to improve the filtration performance. Pre-filters are designed to capture large particles before they reach the downstream 2nd-stage filter, which reduce the dust load on the 2nd-stage filter. The pressure drop of the 2nd-stage filter, therefore, increase slowly with extend life-time. In this study, the loading characteristics of a two-stage filtration system, consisting of a 1st-stage pre-filter and a 2nd-stage main intake air filter, is experimentally evaluated. Three different pre-filter media are used on the 1st-stage, and three common intake air filters are used on the 2nd-stage. Bi-modal aerosols consisting of both super-micrometer coarse mode and sub-micrometer fine mode with varied mixing ratios are employed to challenge the two-stage filter system. The influence of pre-filter to the overall performance of the two-stage system will be investigated for different filter combinations, aerosol compositions, and filtration area ratio between the two stages.

Experimental Single Effect Analysis of the Particle Retention Efficiency of a Gas Scrubber. MICHAEL KLAUCK, Kathrin Trollmann, Jeffrey Kobalz, Robin de Winter, Hans-Josef Allelein, *Forschungszentrum Jülich GmbH*

Avoiding or at least minimizing effects of severe accidents in nuclear power plants on the environment is one of the most essential objectives of Severe Accident Management (SAM). A significant part of the fission products released in the process of a loss of coolant accident can reach the containment – the last dense barrier against the leakage of radioactive isotopes – in the form of airborne particles. Once leaked into the atmosphere, gaseous aerosols accumulate over time and might lead to long-term land contamination. Consequently, reliable prediction of aerosol behavior inside the containment during severe accidents is the key to optimizing SAM and thus to minimizing consequences for the environment. This is of particular relevance when it comes to understanding relevant processes regarding particle retention in a water seal (so-called 'pool scrubbing') which is considered to be one of the processes to efficiently filter the containment atmosphere before venting into the surrounding environment.

Several international reactor safety projects have been studying some partial aspects of pool scrubbing and Filtered Containment Venting Systems (FCVS), e.g. OECD/NEA-THAI 3 and the European Commission-funded PASSAM project. However, in order to develop numerical models based on a phenomenological approach, a broad experimental data base with detailed particle characterization is needed. In the framework of the German national 'SAAB' project ('Severe Accident Aerosol Behavior' 2013-2017, funded by the German Federal Ministry of Economic Affairs and Energy), a sophisticated new test facility has been designed and constructed that allows pool scrubbing-related phenomena to be addressed. Its modular set-up allows the investigation of particle retention efficiency at different pool heights up to 6 m and various options regarding injection geometry. Furthermore, two different concepts provide the opportunity to ensure reproducible and constant aerosol generation for both insoluble and soluble particles. Consequentially, the recently launched follow-up SAAB-II project (2017-2021) aims at providing a reliable data base for model development of water-induced particle retention. Pool scrubbing is investigated focusing on single effect tests and the influence of different boundary conditions, including variations of pool height, injection velocity, temperatures, steam supply, particle size distribution, aerosol composition, and injection geometry.

The paper introduces the SAAB-II project and includes a detailed description of the experimental facility, its measurement instrumentation and the aerosol generators, and gives an overview of the experimental results achieved so far.

Effects of Natural and Modified Attapulgite on the Emission of Ultrafine PM and Heavy Metals during Coal Combustion Process. YISHU XU, Xiaowei Liu, Hao Wang, Yufeng Zhang, Minghou Xu, *Huazhong University of Science & Technology*

$PM_{2.5}$ pollution is one of the most severe environmental issues in China. Ultrafine PM is an important part of $PM_{2.5}$ and is of increasing concerns due to its toxicity and control difficulty. Coal-fired power stations are a primary PM source and are facing with increasing strict emission requirements. Currently, devices such as electrostatic precipitators and fabric filters are implemented to capture and remove the PM in flue gas out of the furnace. Although those devices generally have a total PM removal efficiency of as high as 99.9%, they can not effectively capture the ultrafine PM. So, an in-furnace PM reduction technology has been proposed, which is aimed to reduce the formation of ultrafine during the coal combustion process by adding additives into the furnace.

In this study, clay mineral attopulgite (ATT) was selected as the additive. And another two modified ATT were prepared by HCl and CaCl2 treatments of the natural one respectively. Then, the natural and modified ATTs were separately added into pulverized coal and burn in a drop tube furnace at 1500 °C. To explore their impacts on the ultrafine PM formation, the generated PM was collected via a Dekati low pressure impactor and the mass yields, size distributions, compositions and heavy metal contents of the PM were determined via microbalance, XRF and the microwave digestion-ICP/MS procedure.

The results showed that the natural ATT reduced the mass yield of ultrafine PM by ~27%. By the contrast, the HCl and $CaCl_2$ modified ATT reduced the ultrafine PM by ~44% and ~32% respectively, indicating higher ultrafine PM reduction efficiencies than that of the natural one. What's more, Adding ATT reduced the partitioning of heavy metal (e.g., lead, etc.) into the ultrafine PM and this performance was also improved after HCl modification. These results indicated that the above modification treatments could help improve the capture performance of both ultrafine PM and heavy metals.

2IA.1

Impacts of E-Cigarettes Usage on the Air Quality of Vape Shop and Its Nearby Areas. LIQIAO (VICKY) LI, Charlene Nguyen, Yan Lin, Yifang Zhu, *University of California, Los Angeles*

With the rapid growth of e-cigarette (e-cig) market in the U.S, there is an increasing number of independent retail specialty shops (vape shops) that exclusively sell e-cig. The consumption of e-cig in the vape shop might bring a new emission source for aerosol exposure in its indoor environment and nearby businesses. In this study, we selected a representative vape shop in Los Angeles and recorded the number of vaping puffs in every 10 minutes in the shop for four days. Meanwhile, we measured real-time $PM_{2.5}$ concentration and particle number concentration (PNC) in the vape shop as well as its nearby business (~ 3 m away) and outdoor area (~6 m away). Weekly average nicotine concentrations were also measured in each site. The average concentration (SD) of $PM_{2.5}$, PNC and nicotine in the vape shop was 426 (1283) microgram/m^3, 1.89 (2.14)*10^4 /cm^3, and 1.71 microgram/m^3, respectively, which were much higher than those in nearby business (i.e. $PM_{2.5}$: 16.3 (9.3) microgram/m^3; PNC: 8.42 (19.7)*10^3 /cm^3; nicotine: 1.29 microgram/m^3) and outdoor areas (i.e. $PM_{2.5}$: 17.2 (14.0) microgram/m^3; PNC: 8.96 (5.04)*10^3 /cm^3). The number of vaping puffs were significantly correlated with $PM_{2.5}$ concentration (r=0.74, $p<0.001$) and PNC (r=0.71, $p<0.001$) in the vape shop, indicating the significant contribution of e-cig consumption to indoor aerosols. On the day with the highest average puff number, $PM_{2.5}$ and PNC in the vape shop were significantly correlated with those in nearby business and outdoor area ($p<0.05$), suggesting the impacts of vape shop on nearby air quality. Thus, the secondhand emissions of aerosols in the vape shop potentially impacted on both its and nearby indoor environment.

2IA.2

Indoor PM2.5 in an Urban Zone with Heavy Wood Smoke Pollution: The Case of Temuco, Chile. HECTOR JORQUERA, Lupita Montoya, Francisco Barraza, *Pontificia Universidad Catolica de Chile*

Temuco (38°44’ S, 72°36’ W)) is a mid-size city in southern Chile (south of 35° S) with severe ambient air pollution from wood smoke; however, little is known about indoor air quality there. A measurement campaign at 63 households in the Temuco urban area was conducted in winter 2014. Indoor and outdoor (24-hr) $PM_{2.5}$ and its elemental composition were measured and compared. Infiltration parameters and outdoor/indoor contributions to indoor $PM_{2.5}$ were also determined. A statistical evaluation of how various air quality interventions and household features influence indoor $PM_{2.5}$ was also performed. Air sampling was performed at each household only on workdays (Monday through Thursday) for 24 h. A Minivol sampler (TAS, Airmetrics, Eugene, OR, USA, 5 L/min) was installed in each household to collect $PM_{2.5}$ on a Teflon filter (46.2 mm, PTFE, Whatman, NJ, USA). Simultaneously, outdoor $PM_{2.5}$ levels were measured at a single outdoor site using an ambient $PM_{2.5}$ sampler (Partisol 2000i, Thermos, US, 16.7 L/min). Elemental analysis of indoor/outdoor filters by XRF was carried out at ChesterLab (OR, USA). A survey completed by each head of household included questions about household features such as number and type of cookstoves and heaters, whether the household had undergone a weatherization process and presence of pets or smokers.

Median indoor and outdoor $PM_{2.5}$ concentrations were 44.4 and 41.8 $\mu g/m^3$, respectively. An average infiltration factor (0.62 ± 0.06) was estimated using S as a tracer species. Using a simple mass balance approach, median indoor and outdoor contributions to indoor $PM_{2.5}$ concentrations were then estimated as 12.5 and 26.5 $\mu g/m^3$, respectively. Therefore, 68% of indoor $PM_{2.5}$ comes from outdoor infiltration. This high percentage is due to high outdoor pollution and relatively high household air exchange rates (median: 1.06 h^{-1}).

This study found that S, Br and Rb were dominated by outdoor contributions, while Si, Ca, Ti, Fe and As originated from indoor sources. Using continuous indoor and outdoor $PM_{2.5}$ measurements, a median indoor source strength of 75 µg $PM_{2.5}$/min was estimated for the diurnal period, similar to literature results. In the evening period, the median estimate was 135 µg $PM_{2.5}$/min, reflecting a more intense wood burning at night.

Significant (α=0.10) effects of current interventions and household characteristics on indoor air quality were also found. Concentrations in households heated with woodstoves only were higher than those in households that used a mix of heating fuels, supporting the ongoing woodstove changeout program. Weatherized households reduced the infiltration of species of outdoor origin like S, supporting the ongoing subsidized weatherization program; however, indoor $PM_{2.5}$ was not significantly lower in those households, likely due to indoor $PM_{2.5}$ sources offsetting the reduced outdoor infiltration. In households where wood cookstoves were used, indoor $PM_{2.5}$ concentrations were higher than in households using LPG cookstoves, suggesting that a cookstove improvement program may help decrease indoor $PM_{2.5}$. Indoor $PM_{2.5}$ concentrations in smaller subsidized households tended to be higher than in larger dwellings, reflecting an environmental justice issue that needs to be investigated. Overall, this study presents evidence of a complex indoor/outdoor air quality challenge in Temuco — and in southern Chile as well — requiring a continued and diversified management approach. Further, the ongoing slow decrease in outdoor levels means that improving indoor $PM_{2.5}$ in Temuco through ongoing air quality management policies will likely require an extended period of time.

2IA.3

Indoor Aerosols from Home Heating in the Navajo Nation: Sources, Health Effects, and Control. LUPITA MONTOYA, Wyatt Champion, Paul A. Solomon, Kathleen Stewart, Perry Charley, *University of Colorado Boulder*

A previous study determined that using wood and coal for indoor heating in poorly-maintained stoves likely leads to indoor air pollution and negative health effects in the Navajo Nation (NN) (Bunnell et al., 2010). Emissions from residential wood/coal combustion include fine particulate matter ($PM_{2.5}$), which has been linked to respiratory and cardiovascular disease. They suggested that changing indoor heating behaviors and improving heating stove quality would lead to improvements in indoor air quality (IAQ) and health in this community.

Since IAQ in Native Nations in the U.S. has received very little attention, a series of studies were conducted in response to Bunnell's recommendations. First, the In-Home Heating Alternatives Project (IHAP) assessed in-home heating options for residents of the NN (Champion et al., 2017a). This mixed-methods analysis integrated perception, culture, and technical assessments to provide recommendations for a stove replacement program appropriate for this community. Second, controlled experiments were conducted at the University of Colorado Boulder to evaluate emission factors in terms of mass (*mEF*) and energy (*eEF*) for $PM_{2.5}$, organic and elemental carbon (OC, EC), CO and CO_2 for 2 woods and 2 coals commonly used in the NN (Champion et al., 2017b). A third study evaluated potential oxidative and inflammatory effects of $PM_{2.5}$ generated during the combustion of these 4 fuels utilizing an old stove representative of those used in the NN (Li et al., 2018).

Results from IHAP determined that improved stoves, replacement stoves and passive solar heating were viewed most positively by the Navajo; however, replacement stoves showed the best combined results. In particular, replacement stoves that can combust both wood and coal were recommended. IHAP helped uncover areas where community perception, culture, and the technical analyses align and where there are discrepancies necessitating increased dialogue regarding healthier heating methods. It is necessary that community cultural experts (e.g., Diné Policy Institute) conduct thorough cultural assessments to achieve effective integration of culture and science.

The second study determined emission factors for $PM_{2.5}$, OC, EC, CO and CO_2 for the 4 fuels studied. Results showed that Ponderosa Pine had the lowest *mEF* and *eEF* for $PM_{2.5}$, OC, CO and CO_2. Ponderosa Pine also produced about 50% fewer $PM_{2.5}$ emissions than Utah Juniper during the ignition and warm-up phase. Overall, coal compared to wood produced significantly higher emissions on both mass and energy bases.

The third study determined that Ponderosa Pine wood consistently had the strongest oxidative stress and inflammatory effects. PM components, i.e. low-volatility OC, EC, and soluble Cu, Ni and K were positively correlated with the cellular responses. These findings suggest that $PM_{2.5}$ emitted from combustion of wood and coal commonly used by Navajo residents may negatively impact the health of this community.

Together, these studies informed a heating stove intervention in the NN that includes the option of a new USEPA-certified dual (wood/coal) heating stove, designed specifically for the Navajo. We propose that the framework used for this study may be applicable to other Native American Nations, such as the nearby Hopi Nation, where climate conditions and coal use are similar to those of the NN.

Accuracy of Sensors in Assessing Exposure to Traffic-Related Aerosols. JENNIE COX, Seung-Hyun Cho, Sergey A. Grinshpun, James Ross, Steven Chillrud, Zheng Zhu, Roman Jandarov, Tiina Reponen, *University of Cincinnati*

Traffic-related airborne particles (TRAP) penetrate into buildings affecting the indoor air quality. Improved methods are needed for rapid and accurate assessment of TRAP and the efficiency of control methods. In this study, we evaluated two novel sensors: RTI's Micro Personal Exposure Monitor (MicroPEM) and the MicroAeth real-time black carbon (AE51) sensor. It is recognized in the field that in order to obtain credible real-time measurement results, the data from sensors should be corrected utilizing the information from filter analysis which requires additional time and money. The objective of this study was to create universal correction factors for the MicroPEM and MicroAeth sensors to provide accurate real-time data on PM2.5 and black carbon (BC) in Cincinnati metropolitan area homes, as an alternative to correcting each dataset with the respective filter weights. The two sensors and a PM2.5 impactor (Personal Modular impactor; SKC, Inc.) were collocated in 27 indoor sampling events for 2 days in residences <500 meters from a major roadway and/or had a TRAP score (based on a land-use regression model) of at least 0.33. The PM2.5 impactor samples were analyzed for BC by multi-wavelength integrative sphere method which was gravimetrically calibrated. The real-time PM2.5 concentration from the MicroPEM (RTPM) was averaged and corrected using the gravimetric concentration from the MicroPEM filter. The BC results from the MicroAeth real-time sensor were corrected utilizing BC results from the PM2.5 impactor. Subsets of independent variables in an analysis procedure utilizing multiple linear regression were selected based on lowest Akaike information criterion (AIC). Variables in the model included age and type of building, type of flooring, type of heat (gas or electric), number of smokers, TRAP score, the average daily truck counts within 400 meters, distance to state highways, and distance to a major road (state highways or federal interstates with an average daily truck count of more than 1000). Additional variables of conditions during sampling included season, month, frying food, wood or candle burning, and window opening. The two-day PM2.5 concentrations obtained with the MicroPEM filter ranged from 0.4 to 47.1 $\mu g/m^3$ with a median of 9.5 $\mu g/m^3$. The average correction factor (CF) (MicroPEM filter/RTPM two-day mean) was 1.51 with a coefficient of variation (CV) of 149% (n=27). For the MicroPEM, the final regression model included RTPM values, the average daily truck counts, distance to state highways and distance to federal interstates. By including these variables into the model, the CV was reduced to 40%. The BC values from the PM2.5 impactor ranged from 0.03 to 3.1 $\mu g/m^3$ with a median of 0.4 $\mu g/m^3$. The 48-hour average values from the MicroAeth BC sensor ranged from 0.1 to 2.6 $\mu g/m^3$ with a median of 0.3 $\mu g/m^3$. The average CF (SKC filter/MicroAeth) was 1.3 with a CV of 46% (n=25). Linear regression models considered the variety of variables, but the best model (CV = 49%) did not reduce the CV compared to the correction factor, indicating that these variables are not predictive of indoor concentrations for BC. The poor performance of the models could be due to small sample size and not including other potentially meaningful variables. Still, the PM2.5 model identified three significant factors that indicate the importance of home characteristics for predicting the correction factor. The results from this study will help ensure that the real-time exposure monitors are capable of accurately detecting PM2.5 and BC, which creates the foundation for the further development of user-friendly, field-compatible aerosol instruments for indoor air quality monitoring.

2IA.5

Nanoparticle Resuspension from Surfaces and Resulting Exposures Due to the Use of Consumer Nanosprays in Homes.

RUIKANG HE, Jie Zhang, Gediminas Mainelis, *Rutgers, The State University of New Jersey*

Nanotechnology-enabled consumer sprays are widely used as deodorizers, surface cleaners and for multiple other purposes. These nanotechnology-enabled products release relatively high concentrations of nanoparticles and their agglomerates that may become available for inhalation exposure. This study examined deposition, resuspension, and potential exposures when such nano-enabled sprays are used in a home.

Exposure scenarios examined included adults walking and young children crawling on the floor. The latter was simulated by a robotic crawler. We chose to simulate young children's crawling because their breathing zone is closer to the floor compared to walking. Based on our earlier studies, we selected two Ag-containing and two Zn-containing spray products which generate relatively high mass concentration when applied. The products were applied in a 5 x 9 x 8 ft^3 chamber with controlled background particle concentration. The experiments were performed with carpet and vinyl flooring. Each product was sprayed for 5 min, and particles were allowed to settle on the floor. The particles were resuspended by an adult walking or a robot crawling for 10 minutes every 24 h to determine if resuspension changes over time. Resuspension rate and particle size distributions were measured statically at 0.288 m and 1.1 m above the floor, as well as with a mobile instrument which measured particles in the experimenter's breathing zone during spraying and resuspension. Filter samples were also collected to analyze the morphology and chemical composition of the resuspended particles.

The sprayed particle mass concentration ranged from 0.3 to 58.2 mg/m^3 and the floor-deposited mass density (loading) ranged from 0.00022 x 10^4 to 1.0 x 10^4 mg/m^2. The resuspended particle concentration ranged from 5.2 µg/m^3 to 61 µg/m^3 during walking and from 3.8 µg/m^3 to 9.5 µg/m^3 during robot crawling, depending on the product and floor type. We found that the resuspension rate ranged from 10^{-1} to 10^{-6} h^{-1} and reached a peak value after 24 h for vinyl flooring and after 48 h - 96 h for carpet. As could be expected, the large particles representing agglomerates of sprayed nanoparticle contributed the most to the resuspended particle mass concentration, and small particles were the main contributors to the resuspended particle number concentration. Interestingly, the resuspension rate from the carpet was an order of magnitude higher than that from the vinyl while walking, but only 1.5x higher than that from the vinyl with the robot crawling. Also, the resuspension rate from walking was an order of magnitude higher than that from the robot crawling for both floor types. The resuspended particles and their agglomerates showed the presence of various metals, including Ag and Zn as was advertised in product composition.

Our study shows that when nanotechnology-enabled spray consumer products are used in homes, the sprayed particles not only deposit, but they can also be resuspended from flooring and become available for inhalation exposure. The extent of the resuspension depends on the flooring type, the product, as well as the activity causing the resuspension.

Health Detrimental SVOC Uptake by Infiltrating Ambient Particels Measured with Soot Particle Aerosol Mass Spectrometry. AXEL C. ERIKSSON, Christina Andersen, Anette Krais, Jacob Klenø Nøjgaard, Per Axel Clausen, Aneta Wierzbicka, Joakim Pagels, *Ergonomics and Aerosol Technology, Lund University, Sweden*

Indoor air contains a multitude of health relevant SVOCs originating from active and passive sources. Human exposure occurs continuously, through the relative importance of different exposure routes, some including aerosol particles as intermediate steps, are uncertain. We have studied aerosol particle uptake of a SVOC compound with known adverse health effects; Di(2-ethylhexyl) phthalate (DEHP), from vinyl flooring using in-situ aerosol mass spectrometry. We sampled particles passing through a 1.2 liter aluminum chamber containing 2 dm2 of vinyl flooring with DEHP content of 176 mg /cm3. Mean particle residence times were varied in the interval 1-12 minutes by means of adjusting the flow through the chamber. We used particles infiltrating the aerosol laboratory in Lund for our experiments. We compare our measured aerosol composition with aerosol speciation monitor (ACSM) data from the regional background station Hyltemossa, located approximately 50 km from Lund, in order to separate regional transport from local sources (e.g., particles originating inside the building or city). Furthermore, we injected laboratory generated ammonium sulfate particles for comparison. Our main instrument, used to measure the chemical composition of particles passing though the chamber, was the soot particle aerosol mass spectrometer (SPAMS). We deployed two units in order to investigate the reproducibility of the measurements. We used the "dual vaporizer" mode of SPAMS operation, where the laser vaporizer, which enables soot detection, is periodically disengaged, thus yielding "normal" AMS data intertwined with the SPAMS data. The relative importance of soot containing particles vs non-soot containing particles is thus probed, albeit resulting in non-trivial difficulties in terms of quantification. We used a single particle soot photometer (SP2) to further elucidate the role of soot in the uptake. We used a scanning mobility particle sizer (SMPS) to estimate the surface area available for adsorption. The environmental parameters relative humidity and temperature were monitored. Preliminary results show that the DEHP to total organic aerosol ratio was 5-15% throughout the study period, a total of three weeks. Infiltrating ambient particles were about five times more efficient than laboratory generated ammonium sulfate particles by mass, which we tentatively attribute to increased absorption by the more abundant organic aerosol fraction. Infiltrating particles include a serendipitous event with transported wildfire emissions from the Iberian peninsula (in October 2017), approximately 3000 km upwind our experiment. In addition, there were several events where organic aerosol originating from renovations of the building housing the laboratory was sampled, and what appears to be fresh traffic emissions occurring in the immediate vicinity of the fresh air intake supplying the laboratory. We find that aerosol mass spectrometry is a suitable tool to study the process of health detrimental SVOC uptake by aerosol particles, even in the comparatively clean (PM1 is typically below 5 µg/m3) laboratory air. It is our aim to add more health relevant compounds besides DEHP to coming investigations.

Managing Indoor Air Quality in ClimACT Schools. Susana Marta Almeida, Patrice Blondeau, Vitor Manteigas, Joana Lage, Ana D'Espiney, Marina Almeida-Silva, Nuno Canha, VÂNIA MARTINS, Tiago Faria, Karla Gonçalves, José Luís Alexandre, Ricardo Chacartegui, Jesus Lizana, José António Becera, Ana Gamarra, Yolanda Lechon Perez, Amaia Fernandes, *C2TN, IST, Universidade de Lisboa, Portugal*

The indoor environment of schools where students stay for long periods of time is a matter of primary concern due to the vulnerability and sensibility of children to air pollutant exposure. This work aims to assess the Indoor Air Quality in 38 ClimACT schools located in the Sudoe region of Europe and generate guidelines for a proper management of the schools.

Within the scope of the Interreg Sudoe ClimACT project, Indoor Air Quality audits were performed in 2 classrooms of 38 schools from Portugal, France, Spain and Gibraltar. Levels of PM10, PM2.5, CO2, CO and TVOC were measured with portable direct reading instruments. Passive sampling of volatile organic compounds (benzene, toluene, styrene, tetrachloroethylene, trichloroethylene, m-xylene, o-xylene, p-xylene, 1-4 dichlorobenzene, α-pinene) and aldehydes (formaldehyde, acetaldehyde, acrolein, propanal, butanal, pentanal, isopentanal, hexanal, benzaldehyde) were carried out with Radiello® diffuse tubes. Measurements were performed during one week from Monday to Friday.

PM10, PM2.5, CO_2, TVOC and formaldehyde frequently exceed the guidelines of 20 µg/m^3, 10 µg/m^3, 2250 mg/m^3, 600 µg/m^3 and 30 µg/m^3, respectively. The mean indoor levels of these pollutants ranged as follows: PM10 - 0.04-99 µg/m^3; PM2.5 - 0.03-41 µg/m^3; CO_2 - 882-4381 mg/m^3; TVOC - 0-854 µg/m^3; formaldehyde - 0.10-91 µg/m^3.

The PM10 concentrations measured during the occupied periods were higher than in non-occupied showing that occupancy, through re-suspension of previously deposited particles and possible particle generation, influences the indoor levels of airborne particles. Concentration peaks for TVOC were identified during cleaning activities and during occupied periods due to VOC emissions by occupants (biogenic VOCs, body lotions, etc) and students' activities. Higher CO_2 levels were observed during students' activities inside the classrooms. Even causing negative effects on the students' performance, CO_2 is not classified as a pollutant by the World Health Organization. However, it can be considered a good proxy of insufficient ventilation in classrooms. Therefore, CO_2 can be used to alert teachers to open windows due to the poor air quality or to adjust the amount of outdoor ventilation in Heating, Ventilating and Air Conditioning Systems.

In order to reduce student's exposure to pollutants in classrooms a proper ventilation strategy need to be adopted. Such strategy is even more important in naturally ventilated schools where the air exchange rate is only based on the manual airing of classrooms.

ACKNOWLEDGEMENTS
This work was supported by the European Regional Development Fund (ERDF) through the Interreg Sudoe project ClimACT – Acting for the transition to a low carbon economy in schools – development of support tools (SOE1/P3/P0429). MakerSpaces: An Emerging Indoor Aerosol Exposure Source. Anthony Ramos, Justin Keller, Tim Raymond, DABRINA DUTCHER, *Bucknell University*

MakerSpaces (or HackerSpaces) are facilities with shared tools designed to allow people and groups to come together with the purpose of fabricating devices and sharing ideas. These facilities have increased in popularity in recent years. They are increasingly common in community spaces such as libraries and schools, ranging from elementary schools to universities. Pre-existing spaces, which were not originally designed to be used as MakerSpaces, are sometimes adapted to be a MakerSpace with little consideration of the ventilation system. Tools in these spaces are quite varied ranging from laser cutters to 3-D printers to soldering irons and sewing machines. Many of these tools are known to produce particles, but there is little information available on their impact on the air quality in these spaces. Three MakerSpaces were monitored at Bucknell University with a Scanning Mobility Particle Sizer while tool use was recorded. Each of these facilities is outfitted with different tools and different ventilation system characteristics. Observed particle number concentrations ranged from background level to more than 300,000 particles per cubic centimeter, depending on ventilation rates and tool use. The most significant recommendation stemming from these observations is that MakerSpaces with tools that can be operated remotely (such as 3-D printers and Laser cutters) are not suitable for ventilation systems triggered by occupancy sensors.

2IM.1

Inversion of Scanning Electrical Mobility Spectrometer and SMPS Measurements. RICHARD FLAGAN, Yuanlong Huang, Amanda Grantz, *California Institute of Technology*

The Scanning Mobility Particle Sizer, (SMPS) enables rapid particle size distribution measurements, but the data obtained as the voltage is scanned are analyzed using the transfer function for a constant voltage DMA; that transfer function would be valid for plug flow (uniform velocity within the DMA), but boundary layers within the DMA cause particles to follow different trajectories through the classification region, altering the transfer function. Particles also experience a distribution of time delays between the times when they exit the DMA and are counted by the CPC. Convolution of a delay-time distribution function with the DMA transfer function has been used to invert SEMS/SMPS data, but the distortions caused by the DMA itself are not taken into account. Recent coupling of finite element simulations of the flows and fields within the scanned DMA with Brownian dynamics simulations of the advection, migration, and diffusion of particles during SEMS measurements have revealed additional deviations of the transfer function from that at constant voltage.

Prompted by these results, we have re-examined SEMS/SMPS data inversion, which requires: (i) a transfer function for the instrument; (ii) a model that will be used to represent the resultant particle size distribution function; and (iii) an algorithm that will be employed to solve the inverse problem to deduce the size distribution that best represents the collection of signals acquired during the measurement. At constant voltage, the physics-based, Stolzenburg model of the transport and diffusion of particles within the DMA accurately describes the instrument. The delay time distribution caused by can be approximated the residence time distribution from one or more so-called continuously-stirred tank reactors combined with a fixed delay. The new transfer function for the TSI long-column DMA reveals a delay-time distribution within the classification region, and a more complex downstream delay time distribution that the previous models suggest. Combined with empirical transmission and detection efficiency functions and theoretically predicted charge distributions, these refinements reproduce the time and size variation in particle transmission through and detection by the SEMS/SMPS measurement system and form the foundation for data inversion. The computational effort to obtain the real-instrument transfer function is, however, large. We have, therefore, undertaken the development of a theoretical transfer function for the scanned-voltage DMA analogous to the Stolzenburg transfer function for the static DMA, and that is more readily applied to other DMA operating conditions, and to different DMA designs.

The discretized form of the particle size distribution also strongly affects the data inversion. Multimodal lognormal distributions impose a potential shape bias on the size distribution. Representation as a set of discrete particle sizes (delta functions) or as a histogram representation are also commonly used. Linear splines are used in a number of algorithms. Higher order basis functions can also be used. The degree of approximation directly impacts the quality of the data fit obtained. The algorithms employed can also affect the quality of the inversion. In this study, we examine the sensitivity to different models for the same instrument, size distribution representations, and inversion algorithms in order to understand their effects on the recovered distributions. While the focus of this study has been on SEMS or SMPS data inversion, the results have implications for all methods used to determine aerosol particle size distributions.

Improving the Accuracy and Precision Of Sub-10 nm Atmospheric Nanoparticle Measurements with a New High Flow DMPS. JUHA KANGASLUOMA, Lauri R. Ahonen, Tiia M. Laurila, Runlong Cai, Joonas Enroth, Stephany Mazon, Frans Korhonen, Pasi Aalto, Markku Kulmala, Michel Attoui, Tuukka Petäjä, *University of Helsinki*

Measurement of atmospheric sub-10 nm nanoparticle number concentrations has been of substantial interest recently, which, however, is subject to considerable uncertainty that has not been examined thoroughly. We report a laboratory characterization of a high flow differential mobility particle sizer (HFDMPS), which is based on the SEADM Half-mini type differential mobility analyzer (DMA) and Airmodus A11 nano condensation nuclei counter, and show the first results from atmospheric observations from Hyytiälä, Finland during spring of 2017. The HFDMPS utilizes the state-of-the-art aerosol technology, and is optimized for particle size distribution measurements in the sub-10 nm size range by a moderate resolution DMA, optimized and characterized low-loss particle sampling and minimal dilution in the detector.

We analyze the performance of the HFDMPS in two aspects: the instrument is analyzed in terms of the PtQ value, which directly connects the instrument performance to the number of counted particles. PtQ is shown to be useful parameter is determining the instrument detection limit and, when combined with the DMA sizing resolution, measurement uncertainties.

Further, we present an exhaustive laboratory calibration to the HFDMPS and compare the inverted atmospheric particle number concentrations to the long-term size segregated aerosol number size distribution measured with the Hyytiälä long-term DMPS. Because of the optimized sampling and higher sensitivity of the HFDMPS, it detects about two times more 3-10 nm particles than the long-term DMPS, and by having better counting statistics by a factor of 3.5-9 depending on the size, the counting uncertainties are reduced about 50% as compared to the long-term DMPS. The HFDMPS did not observe any sub-2.5 nm particles in Hyytiälä, and the reason for that was shown to be the inability of DEG to condense on such small biogenic particles, instead of lack of sensitivity. Last, we discuss the general implications of our results to the sub-10 nm DMPS based measurements.

Characterization of the Boosted 3776 Butanol TSI CPC in the Sub 2 nm Range. Activation of Sub 2nm Particles with Butanol.

MICHEL ATTOUI, *LISA Paris Est Creteil University France*

Boosted butanol laminar sheathed condensers CPCs have (Kuang2012) demonstrated their ability to detect sub 3 nm with acceptable detection efficiency although lower than mixing cpc with di ethylene glycol as working fluid. In the other hand Kangasluoma et al. 2015 have showed than unsheathed condensers butanol CPCs are able to detect particles down to 1 nm. So if unsheathed condenser can detect particles of 1 nm why not the sheathed condenser CPC design? The abilities of this CPC in terms of flowrates control (sheath and capillary) are used to study the activation (or no activation) of THABr and TBABr monomer by lowering the aerosol losses in the capillary and working at the limit or threshold of the homogeneous nucleation.The presentation gives the effect of the flowrate in the capillary on the detection efficiency for different temperatures difference DTs between the saturator and condenser until the limit of the homogeneous nucleation. The figures 1 and 2 below give the inverse mobility spectra of TBABr (tetrabutylammonium bromide) with flowrates of 50 cc/min 70 cc/min in the capillary at the limit of the homogeneous nucleation and respectively in the condenser. The figures 3 and 4 give the results with THABr (tetraheptylammonium bromide) in the same with 50 et 70 cc/min aerosol flowrate in the capillary at the limit of the homogeneous nucleation always.

Penetration Efficiency of Sub-3 nm Particles in the Sampling Line of an Electrical Mobility Size Spectrometer. YUEYUN FU, Mo Xue, Runlong Cai, Juha Kangasluoma, Jingkun Jiang, *Tsinghua University*

Due to the high diffusivity of sub-3 nm particles, their diffusion loss through the instrument sampling line is large. In addition, the often used Gormely-Kennedy (G-K) formula for penetration efficiency through a straight cylindrical tube may fail for sub-3 nm particles. The G-K formula is an asymptotic analytical solution of the convection diffusion equation and is applicable when particle concentration at the inlet is uniform. However, the boundary conditions used to derive the G-K formula are usually violated in practical use, especially for sub-3 nm particles. In addition, when the flow field changes in the sampling line, particle concentration will redistribute in the cross-sectional profile that may result in larger concentration gradient near the wall and thus additional particle loss. Thus, penetration efficiencies through three-way connectors, elbows, bends, and core-sampling tubes can be different from values predicted by the G-K formula. Experiments and numerical simulation were performed to study the penetration efficiency of sub-3 nm particles through the sampling line of an aerosol electrical mobility spectrometer. Straight cylindrical tube, elbow, three-way connector, and core-sampling tube were characterized. The penetration efficiency through a soft X-ray neutralizer and a DMA were also evaluated. Strategies to improve the sampling efficiency of sub-3 nm particles were tested. For instance, properly designed core sampling tube (2 LPM core-sampling flow, 8 LPM transport flow, 60 cm in length) can increase the sampling efficiency of 1.5 nm particle by 26%, comparing to a straight cylindrical tube with the same length and total flow. The penetration efficiencies through each parts of the spectrometer sampling line were integrated together to properly recover size distributions of sub-3 nm particles.

A Modified Real-Time Method to Measure Particle Geometric Surface Area with a Time Resolution of 1s. LIPENG SU, Qisheng Ou, Leo N.Y. Cao, David Y. H. Pui, *University of Minnesota*

This paper reports the improvement of a real-time method to measure geometric surface area (GSA) of nanoparticles with a higher precision and an improved time resolution of 1s. In this method, a unipolar diffusion charger was used, followed by two identical systems in parallel, both consisting of an ion trap and an electrometer. By applying different voltages on the two ion traps, charged particles with different electric mobility may penetrate through the corresponding ion trap, with the carried charges measured by the electrometer downstream. The two measured electric currents were combined in a biquadratic subtractive process to achieve linear correlation with GSA of nanoparticles precisely. To validate the newly developed method, laboratory tests and field measurements were carried out by combined measurement using above-mentioned system and a Scanning Mobility Particle Sizer (SMPS) simultaneously. Good agreements were found between the two sets of instruments, with the improved unipolar charging technique having better time resolution of 1s.

Aitken's Condensation Counter: Bringing History to Life. DYLAN LEIGH-MANUELL, Suresh Dhaniyala, *Clarkson University*

John Aitken, a late 19th century meteorologist, physicist, and engineer, began his research into condensation and phase transformations in 1875. In 1890, this research led to the development of the Aitken dust counters, considered to be the first condensation nuclei counters. Because of their small size, simplicity, and ability to generate reproducible measurements, Aitken's dust counters, the pocket dust counter in particular, became widely used for the next half a century. This presentation outlines how John Aitken's early condensation nuclei counters were able to optically count particles in the air. We will also describe the process taken to restore an original Aitken Portable Dust Counter along with an original Aitken Pocket Dust Counter to working order. Lastly, we test the two historical counters and compare their performance in measuring aerosol concentrations to modern day instruments.

2IM.7

Application of Size-Independent Charging of Nanoparticles for Improving DMA-Classification Performance. Yoohyun Ock, Jeonggeon Kim, Mansoo Choi, DONGGEUN LEE, *Pusan National University*

The goal of this study was to achieve a significant improvement in the size-selection performance of DMA, by combining unipolar charging and the condensational method of growing nanoparticles. We developed a size-independent unipolar charger consisting of a saturator, a condenser, a corona charger, and an evaporator. Starting with a two-fluid mixing design, a porous-alumina-lined saturator was tested in terms of the size uniformity of particles after their condensational growth in a subsequent condenser. 20-nm Ag and 65-nm NaCl polydisperse nanoparticles were successfully grown into droplets of few micrometers with a geometric standard deviation of 1.20 or less. A simple model was also developed to explain the heat and mass transfer occurring in the saturator and condenser, resulting in predictions of particle growth that agreed with experimental results. The entire charging system was experimentally evaluated in terms of size dependencies of charging efficiency and charge numbers. The results revealed that ~52% of the nanoparticles were uniformly charged with a charge number of +32, irrespective of the particle sizes. A regular nano DMA, using the proposed size-independent charging system in place of a bipolar charger, was finally tested to determine its productivity when size-classifying particles. It was found that the proposed charger was eight times more efficient for DMA size selection compared to the bipolar charger, and became more advantageous as the target particle size decreased. These promising results were reconfirmed by TEM image analysis of the produced monodisperse particles.

2IM.8

A Versatile Portable Exhaust Particle Sampling System to Extend Particle Number Measurements below 23 Nanometers. MARKUS BAINSCHAB, Alexander Bergmann, Panu Karjalainen, Jorma Keskinen, Jonathan Andersson, Athanasios Mamakos, Tero Lähde, Christoph Haisch, Oriana Piacenza, Ananias Tomboulides, Zisimos Toumasatos, Leonidas Ntziachristos, Zissis Samaras, *Graz University of Technology*

Modern and near-future combustion engine vehicle technology may emit notable levels of particles below the current particle size threshold (23 nm) of the European Particle Number (PN) emission standards. The Horizon 2020 funded project DownToTen (DTT) is developing a sampling and measurement methodology to characterize exhaust aerosol emissions down to at least ten nanometers. This study presents the first prototype of a portable exhaust particle sampling system (PEPS) developed in the framework of the project.

Laboratory experiments, in which various dilution systems were challenged with aerosols from a variety of sources, showed that a double porous tube dilution (PTD) system is the method offering the lowest detectable size. The radially inflowing dilution air in a PTD reduces thermophoretic and diffusional losses of <23 nm particle sizes and the compact all-metal design facilitates the realization of a heated dilution stage. The first porous tube is supplied with hot (350°C) dilution air. The second PTD operates at room temperature. Dilution may be combined with different conditioning chambers, depending on purpose: an aging chamber to thermodynamically stabilize aerosol, an evaporation tube or a catalytic stripper to isolate non-volatile particles, or a photo-oxidation chamber to address secondary aerosol formation. Sample flowrates and dilution ratios settings are controlled by mass flow controllers.

The system is characterized with laboratory and real exhaust aerosols in terms of particle losses and dilution ratio stability. Computational fluid dynamics (CFD) simulations provide detailed insights on the air flow through the porous medium, and the mixing of the dilution air and the sample flow. Further, the propagation of pressure pulses and their impacts on the dilution ratio is examined. Two different laboratory experiments were conducted to validate the pressure pulsation results of the CFD simulations. The first uses an aerosol source with a controllable pressure level, and uses pressure sensors with high temporal resolutions at various spots in the dilution system to show how pressure pulsations affect the dilution ratio and the performance of downstream particle number measurement devices. The second experiment uses an ultrasonic transit time flow meter to inspect the sample flow downstream of the porous tube diluter to check for high frequency flow fluctuations predicted by the simulations. Finally, the sampling system is employed for engine exhaust measurements on a chassis dynamometer.

The comparison of the developed dilution system with the commercial measurement systems fulfilling current EU PN Regulation demonstrates the feasibility of the DownToTen PEPS for sub 23 nanometer engine exhaust particle number measurements. The versatile tests with laboratory particle sources and the measurements of vehicle exhaust particles suggest that DTT PEPS extends the exhaust particle measurement range down to 10 nm and below reliably.

2IN.1: INVITED

Ice Nucleating Particle Properties Relevant to Aerosol Cloud Interactions in the Himalaya Region. Shweta Yadav, Rebecca Venezia, Ryan Paerl, MARKUS PETTERS, *North Carolina State University*

The foothills of the Himalaya mountains are often blanketed by a thick haze layer that originates from anthropogenic and natural sources. There is a dearth of data on ice nucleating particle (INP) concentrations within these airmasses, thus limiting modelling studies that try to assess the influence of INPs on ice cloud formation. Here we present new data on INPs measured from filter and precipitation samples collected in rural and urban locations of northern India, including the states of Jammu & Kashmir, and Himachal Pradesh. In addition, we characterize the INP properties of mineral dust samples obtained from the Thar Desert, which is located in the northwestern part of the Indian subcontinent. Ice nucleation activity was obtained using the cold-stage technique. For the ambient samples, fluorescent particle size and concentration were determined using multi-wavelength flow cytometry. Factors that influence INP concentrations are explored. Results show that rainwater-derived INP concentrations are similar to the lower bound of observations obtained over the North American continent. Strong signals from pollution or bioaerosol were not evident. Ice nucleation active site density of Thar Desert dust, normalized by the geometric surface area of the aerosol, was similar for mobility-selected sizes ranging from 200-600 nm. Furthermore, the Thar Desert dust is well described by parameterizations that were built from dust data collected elsewhere around the globe. These data suggest that local pollution is not a strong source of INPs over the northern Indian subcontinent. Furthermore, existing dust parameterizations can be applied to estimate INP concentration if information about suspended dust surface area is available.

2IN.2: INVITED

Influence of Heterogeneous Ice Nucleation of Sea Spray Aerosol on Southern Ocean Clouds. CHRISTINA MCCLUSKEY, Paul DeMott, Thomas Hill, Kathryn Moore, Sonia Kreidenweis, Ruhi Humphries, Alain Protat, Greg McFarquhar, Susannah Burrows, Andrew Gettelman, *National Center for Atmospheric Research*

Clouds occurring over the Southern Ocean (SO) are often comprised of supercooled liquid and are abundant, with an annual average cloud fraction greater than 0.8. Global climate models fail to simulate SO cloud phase and lifetime, leading to large Southern Hemisphere energy biases in climate model simulations. It is hypothesized that these shortfalls are due to poor numerical representations of ice phase transitions and ice microphysics. In a series of observational and modeling studies, we have characterized ice nucleating particle (INP) populations over the SO and investigated their role in primary ice nucleation and subsequent cloud glaciation in a global climate model.

Two methods were used to determine immersion freezing INP number concentrations (n_{INPs}); 1) the ice spectrometer, an offline immersion freezing technique and 2) the continuous flow diffusion chamber, an online INP measurement. These two methods were deployed onboard the Australian Marine National Facility RV Investigator as part of the Clouds, Aerosols, Precipitation, Radiation and atmospherIc Composition Over the southeRN ocean (CAPRICORN) voyage from March to April in 2016. These data represent the first survey of INPs over the SO region in over four decades. Extraordinarily low n_{INPs} were observed in this unique region, with no more than 1 INP active at -30 °C per liter of air. Using the atmospheric component (community atmospheric model, CAM5) of the DOE Community Earth System Model with implementation of a physically-based parameterization for sea spray organic aerosol, simulations using nudged meteorology were conducted for the CAPRICORN study period. Modeled aerosol mass, number and composition were used as input for various parameterizations proposed for predicting n_{INPs}. Estimates of n_{INPs} were in agreement with field observations and results demonstrated that a recent empirical marine INP parameterization may be used to predict observed concentrations of nINPs from the CAPRICORN project.

These new observational constraints and a marine INP parameterization allow for modeling studies to investigate the influence of INPs and primary ice nucleation on cloud phase in SO clouds. As such, the NCAR community atmospheric model (CAM5) will be used in a series of sensitivity simulations designed to explore different representations of INPs and subsequent primary ice nucleation. Simulated cloud occurrence and phase will be directly compared to ship and aircraft based observations, including comprehensive measurements of aerosol and cloud properties, made during the Southern Ocean Clouds, Radiation, Aerosol Transport Experimental Study (SOCRATES) from January to February 2018.

2IN.3: INVITED

Surface Chemistry of Ice Nucleating Mineral Dust Particles. ALEXEI KISELEV, Alice Keinert, Alexei Nefedov, Weijia Wang, Christof Woell, Thomas Leisner, *Karlsruhe Institute of Technology*

Heterogeneous ice nucleation on the surface of mineral dust particles is an important process responsible for the ice formation in atmospheric clouds. Recently, the surface topography and crystalline structure have been recognized as the two major factors defining the ice nucleation efficiency of K-feldspar, a very common aluminosilicate mineral abundant in the atmosphere as a universal component of airborne mineral dust particles. However, the chemistry of the mineral surface in contact with supercooled water or ice remains poorly characterized due to the lack of experimental methods sensitive to the water-mineral interface. Several questions have to be answered to complement the picture of heterogeneous nucleation, such as the importance of surface charge, the role of framework cations, protonation state of the mineral surface, and the role of ionic species dissolved in water.

In this contribution, we address some of these questions by conducting water freezing experiments on the well-defined surfaces (thin sections) of alkali feldspars with various crystallographic orientations. We show how their freezing efficiency can be predictably modified by treating the surface by argon plasma of different density. We further investigate the chemical composition of the samples in the environmental scanning electron microscope (ESEM) by means of X-ray energy and wavelength dispersive spectroscopy (EDS and WDS), as well as with ultra-high vacuum IR adsorption spectroscopy and X-ray photoelectron spectroscopy (XPS). The measurements conducted with these surface sensitive analytical methods allow us to make certain conclusions about the role of surface chemistry and the particular importance of hydroxyl groups in the nucleation of ice on mineral surfaces. Moreover, these findings offer a possibility of bridging the gap between the atomistic simulations and laboratory experiments, with the ultimate goal of creating a molecular dynamic model of heterogeneous ice nucleation on realistic substrates.

2IN.4

Mineral Dust Aerosol Measurements throughout the Global Free Troposphere and Implications for Cirrus Formation.

KARL D. FROYD, Daniel Murphy, Gregory Schill, Agnieszka Kupc, Christina Williamson, Charles Brock, Pengfei Yu, Karen Rosenlof, Huisheng Bian, Mian Chin, Peter Colarco, *NOAA ESRL and CIRES, University of Colorado Boulder*

Lab and field studies indicate that mineral dust particles are efficient ice nuclei, and recent airborne measurements confirm the dominant role of dust on cirrus cloud formation in the northern hemisphere. However, the net climate impact of mineral dust is not well constrained in part due to the lack of dust abundance measurements above the Earth's surface. We present new airborne mineral dust measurements from the 2016-2017 NASA ATom (Atmospheric Tomography) campaigns that cover the entire Pacific and Atlantic basins from the boundary layer through the free troposphere. This global dataset fills a critical measurement gap for dust in the background upper troposphere. Measured concentrations are compared to global simulations of dust aerosol, with a focus on model accuracy at cirrus altitudes. We identify source contributions to the remote troposphere and examine mechanisms of vertical transport and removal. Using heterogeneous nucleation efficiencies from laboratory studies, we estimate that background dust particles can contribute to cirrus formation throughout wide regions of the global upper troposphere. In particular we explore north-south hemispheric gradients of dust aerosol and the implications for differences in cirrus properties.

Immersion Freezing Efficiency of Airborne Mineral Dust at Various Particle Size-classes. NAAMA REICHER, Shira Raveh-Rubin, Yinon Rudich, *The Weizmann Institute of Science*

Mineral dust is a prominent atmospheric aerosol, affecting clouds microphysics and climate by its ability to act as cloud condensation nuclei (CCN) or as ice nucleating particles (INP). Mixed-phase clouds, which contain both supercooled droplets and ice crystals, are highly sensitive to the presence of INPs since they can trigger instant glaciation. It is still not well understood how nucleation is facilitated by the dust surface, but it was shown that mineralogy plays a crucial role in determining the efficiency of the ice nucleation process. Feldspars, for instance, were identified recently as highly efficient INPs, compared with other abundant mineral phases, such as clay minerals (illite, montmorillonite and kaolinite), calcite or quartz. Moreover, different types of feldspars also differ in their ice nucleation efficiency and active temperature regions. Therefore, the prediction of ice nucleation efficiency of different dust events depends on the mineral composition of the dust, which can vary according to the geographic source of the dust, the particle size and changes in its mineralogy during atmospheric transport. In order to examine the effect of the particle size on ice nucleation efficiency in ambient samples, airborne mineral dust was sampled during dust events from two source regions, the Sahara Desert and the Syrian Desert. The particles were collected and size-segregated using micro-orifice uniform deposit impactor (MOUDI) during five dust storm events. The collected particles were immersed in nL-size water droplets using microfluidics technique, and ice nucleation properties were studied using the WeIzmann Supercooled Droplets Observation on Microarray (WISDOM). We found that ice nucleation efficiency was similar for the different dust sources, but varied with particle size. In all but one event, the freezing efficiency of larger particles was higher, and supermicron particles exhibited higher ice nucleation efficiency in comparison with the submicron particles. Moreover, active site density spectra (ns) of supermicron particles were similar to the spectra obtained for standards of feldspar minerals, suggesting that this size fraction is more characterized by feldspars. In the event where particles size did not affect the ice nucleation efficiency, the total efficiency was lower than that measured in the other dust events, and this was attributed to a nearby biomass-burning event, which contributed biomass-burning aerosols to the sample or interacted with the mineral dust surface. These results suggest that mineralogy change with the particle size and that further characterization of the mineralogy difference with atmospheric transport is needed to better establish our prediction of ice nucleation efficiency of atmospheric dust.

2IN.6

Effect of Mineralogy, Particle Size, and Composition on the Immersion Freezing Properties of Three Central American Volcanic Ashes. LEIF JAHN, Daniel Williams, Michael Polen, William Fahy, Ryan Sullivan, *Carnegie Mellon University*

Ash generated from explosive volcanic eruptions represents a large source of material periodically injected into the atmosphere. Recent studies have suggested that volcanic ash is a potentially significant source of ice nucleating particles (INP). However, the current body of research regarding how the chemical composition of volcanic ash relates to its ability to nucleate ice is lacking, especially in atmospherically relevant particle size ranges. In this work, we analyzed three volcanic ash samples collected in the vicinity of recent volcanic eruptions (Volcàn de Fuego, Guatemala, 2015; Santiaguito, Guatemala, 2011; Soufrière Hills, Montserat, 2011). Each of the samples were sieved to a <37 µm size fraction, and the Fuego sample was further separated into <2.5 µm, 2.5-10 µm, and 10-37 µm fractions using a custom dust generator and MOUDI sampler. X-ray diffraction (XRD) analysis indicates that the ashes are mostly composed of Na- and Ca-rich feldspars, as well as varying amounts of silica polymorphs and pyroxenes. Additionally, XRD was used to quantify the amount of amorphous non-crystalline material, which likely has weak ice nucleation ability. Freezing properties were examined in the immersion mode using a droplet freezing cold plate. Analysis of the droplet freezing temperature spectra shows that the ashes contain efficient INP in the range of -10 to -25 °C that are consistent with the presence of feldspars—some of the most ice-active mineral phases. The Fuego ash sample demonstrated freezing ability comparable to that of some of the most ice-active K-rich feldspar samples reported in the literature, which we attribute to the presence of Na-rich/K-poor anorthoclase feldspar. Additionally, smaller particle sizes were observed to be more ice-active, even when accounting for differences in particle surface area. Ash elemental composition at the population level was examined through ion chromatography, and individual particle elemental distribution and morphology was examined through scanning electron microscopy. Our results indicate that these volcanic ash aerosols can be a significant source of INP and that this freezing ability is driven by the crystalline phase content, mineralogy, and quantity of feldspar minerals in the ash.

2IN.7

Ice-Nucleating Properties of Coal Fly Ash Particles in Cirrus Cloud Conditions. NSIKANABASI UMO, Robert Wagner, Romy Ullrich, Kristina Höhler, Naruki Hiranuma, Amanda Lea-Langton, Harald Saathoff, Alexei Kiselev, Peter G. Weidler, Heike Wex, Sarah Grawe, Jenny M. Jones, Alan Williams, Benjamin Murray, Thomas Leisner, Ottmar Möhler, *Karlsruhe Institute of Technology*

Globally, over 600 Tg of coal fly ash (CFA) are produced annually from coal combustion for industrial and domestic energy production. A certain proportion of these aerosol particles is emitted to the atmosphere and may impact air quality, human health, and radiative transfer through the atmosphere. Coal fly ash can also modify cloud microphysical and optical properties, hence influencing the climatic and the hydrological cycles. However, our understanding of the role of CFA in nucleating ice at conditions relevant to cirrus clouds is lacking and requires research efforts. Here, we investigate the ice-nucleating properties of CFA, obtained from four different sources, in the deposition mode at the AIDA (Aerosol Interaction and Dynamics in the Atmosphere) cloud simulation chamber. All the CFA samples (particle median diameter ~ 0.6 µm) showed significant ice nucleation activity at ice saturation ratios between 1.04 and 1.38 evaluated at the maximum relative humidity with respect to ice reached during each experiment, in the temperature range from 214 K to 251 K. The ice nucleation active surface site densities of these particles in the deposition mode were estimated between 10^9 - 10^{11} m^{-2} within the same temperature coverage of the experiment. One of the CFA samples studied in this work showed high ice nucleation activity at even lower ice saturation ratios (1.04 - 1.16) at ~ 228K, which suggests that pore condensation and freezing may be the dominant ice formation mechanism as there was no corresponding high activity of this particular CFA in the immersion freezing mode. The results from this study have clearly established that CFA aerosol particles efficiently nucleate ice in the deposition mode. Future study should focus on probing the factors driving their ice-nucleating abilities. CFA particles may contribute to cloud ice formation, in particular, close to the source region where these particles are emitted directly into the atmosphere. Also, future modelling and experimental studies are needed to further investigate and assess the abundance of CFA aerosols and their contribution to cloud ice formation on regional and global scales.

2IN.8

Characteristics of Ice Nuclei in the North China based on Mountain Measurements. KAI BI, Xincheng Ma, Fei Wang, Yunbo Chen, Ping Tian, Quan Liu, Delong Zhao, Gavin McMeeking, Ezra Levin, *Beijing Weather Modification Office*

Ice nuclei measurements were conducted at Haituo Mountain in northwest Beijing in 2016-2017 winters. The characteristics of wintertime ice nuclei particles (INPs), as well as their relation with meteorology elements and atmospheric aerosols were investigated with a continuous flow diffusion chamber (CFDC) and a Bigg mixing cloud chamber. Relationships between pollutants and IN number concentrations were also studied. The results showed that the concentration of Ice nuclei particles(INPs) active at -10℃~-25℃ typically ranged from 0.2#/L~64.8#/L with Bigg Chamber. The INPs active at -15℃~-35 ℃ at water supersaturation 5% ranged from 0.5#/L~362.4#/L with CFDC. The INPs active at -25 ℃ and water supersaturation -5%~5% were from 2.5 #/L ~54.9 #/L. The relationship of INPs and T match the exponential distribution, as f(T)=0.0016583*exp(-0.43353*T). INPs did not increase obviously in heavy polluted days comparing to clean days. The INPs increase after snow in 2/3 of snow cases. Of all meteorological elements, wind speed and airflow direction appeared to influence IN number concentrations.

2MS.1

A Facile Aerosol-based Synthesis of Cu-Ce-O Hybrid Nanoparticles for Synergistic Catalysis of Methane Combustion.

DE-HAO TSAI, *National Tsing Hua University*

The synergistic effect of Cu-Ce-O hybrid nanostructure has shown the promise for catalytic methane combustion. Here, we aim to develop an aerosol-based two-stage thermal treatment method to (1) synthesize the Cu-Ce-O hybrid nanoparticle (NP) with a tunable oxidation state directly in gas phase, and (2) provide a mechanistic understanding of surface reduction of the Cu-Ce-O hybrid NP for catalysis of methane combustion. After evaporation-induced self-assembly followed by a thermal decomposition (i.e., 1st stage) to form metal oxide NP at the 1st stage thermal treatment, a temperature-programmed, aerosol-based hydrogen reduction process was employed for direct tuning the oxidation state of the NP in the gas phase (the 2nd stage thermal treatment). Differential mobility analysis, x-ray diffractomery, x-ray photoelectron spectroscopy, and scanning electron microscopy were employed complementarily for characterization of particle size, morphology, crystallinity, elemental composition, and oxidation state of the NPs. The results show a successfully catalysis on methane combustion over various initial oxidation states of Cu through the hybridization with ceria . The results show a high activity with a low light-off temperature, a high light-off stability and operation stability toward catalytic methane combustion. The prototype method is especially useful to fabricate a variety of nanocatalysts with different oxidation states of active metals by design for the study of methane-based energy and environmental applications.

2MS.2

Measurements and Simulations of Nanomaterial Formation and Gas Phase Intermediates' Behavior in Buoyancy Opposed Flame Synthesis Reactor. IGOR RAHINOV, Johannes Sellmann, Sebastian Kluge, Hans Juenger, Alexey Fomin, Matthieu Raphael Lalanne, Sergey Cheskis, Christof Schulz, Hartmut Wiggers, Andreas Kempf, Irenaeus Wlokas, *The Open University of Israel*

Production of the iron oxide nanoparticles with tailored properties by flame-assisted synthesis should rely on detailed understanding of the mechanisms governing their formation and nucleation from the gas phase. Specifically, nanoparticle formation in flames is strongly influenced by the residence-time–temperature history inside the flame [1,2]. We study how the temperature history can be intentionally modified by orienting flames either in an upward-firing or downward-firing configuration. We also investigate the influence of unintended residence-time modifications caused by sampling nozzles. These phenomena are investigated by experiments and simulations for the synthesis of iron oxide nanoparticles from premixed iron-pentacarbonyl-doped hydrogen/oxygen flat flames[3,4]. The experiments apply molecular-beam sampling with a particle mass spectrometer to measure particle sizes and a quartz microbalance to detect the presence of condensed matter [5]. Laser-Induced Fluorescence (LIF) and Intracavity Laser Absorption Spectroscopy (ICLAS) were applied to monitor gas-phase Fe and FeO, respectively[4,6,7]. The simulations rely on a finite-rate chemistry approach with detailed diffusion, particle dynamics are described by a bi-modal population balance model. The results revealed a strong impact of the reactor orientation on the velocity field. It is demonstrated that the downward-burning flame forms a detached stagnation point, causing longer residence times at elevated temperature than an upward- or horizontally firing flame, permitting the growth of larger particles. These iron oxide particles are eventually formed in the recombination zone of the flame, but no condensed matter was found in the reaction zone. In presence of a probing nozzle, the overall shape of the flame changes, depending on the distance of the probe from the burner dramatically. The corresponding residence times are also strongly affected by the probe. Due to strong stagnation effects the 1-D model cannot be applied directly to this "nominally flat" flame configuration. Rather, the experimentally determined Fe and FeO concentrations were compared to outputs of detailed reaction mechanisms in one-dimensional models using the previously determined flow field. This allowed to draw suggestions for further optimization of iron-chemistry mechanism.

Synthesis of Crumpled Graphene Nanostructures Decorated with Multicomponent Metal Nanoparticles in a Flame-driven High Temperature Reducing Jet Reactor. MOHAMMAD MOEIN MOHAMMADI, Santosh Srivatsa Gunturi, Shikuan Shao, Raymond Buchner, Mark Swihart, *University at Buffalo - SUNY*

Among carbonaceous materials, graphene has become attractive because of its unique properties such as high specific surface area, good electrical conductivity, flexibility, and high mechanical strength. The most common synthesis method of graphene is based on graphite oxidation to graphene oxide (GO) followed by thermal or chemical reduction of GO to reduced graphene oxide (rGO). In thermal reduction methods, a small amount of GO is typically placed in a high temperature inert or reducing environment for a specific time. In addition, to improve certain properties or to add new features, rGO is decorated with other compounds which usually requires additional synthesis steps. Here, we demonstrate the continuous single-step synthesis of three-dimensional crumpled graphene (CG) nanostructures decorated with multicomponent metal nanoparticles including CG-cobalt-nickel and CG-iron-cobalt-nickel using the High Temperature Reducing Jet (HTRJ) process. In this process, combustion products of a fuel-rich hydrogen flame pass through a converging-diverging nozzle. An aqueous solution or dispersion of precursors injected at the throat section of the nozzle is atomized by the hot high-velocity gas stream. The resulting droplets evaporate in reducing environment containing excess H_2. After the reaction zone, products are cooled immediately and collected on a filter paper. The key advantage of the HTRJ system over common flame-based aerosol synthesis methods is the separation of flame and product formation zones, which allows synthesis of nanomaterials that can be reduced by H_2 in the presence of H_2O. We have utilized the capabilities of this system to synthesize CG nanostructures using an aqueous dispersion of GO as the precursor. Moreover, by adding nickel, cobalt, and ferric nitrate salts to the GO precursor solution, we decorated CG nanostructures with iron-cobalt-nickel nanoparticles of less than 10 nm average diameter. The HTRJ process is a potentially scalable, continuous synthesis method of CG and CG-metal nanostructures. The nanostructures made by this process can be used in electrocatalysts for fuel cells, electrodes in batteries and supercapacitors, conductive inks for printed electronics, and in many other applications where a graphitized carbon-metal nanomaterial is needed.

Tailored Synthesis of Macroporous Pt/WO3 Nanoaggregates via Flame Spray Pyrolysis and Their Photocatalytic Properties. OGI TAKASHI, Ghana Rinaldi Febrigia, Tomoyuki Hirano, Kikuo Okuyama, *Department of Chemical Engineering, Hiroshima University*

A high surface area is a key feature of nanoparticles, and enhances their performances in many applications, including photocatalysis. However, handling nanoparticles is more difficult than handling micron- or submicron-sized particles. It has been reported that exposure to large amounts of nanoparticles over a long time period can harm human health and the environment. One strategy for addressing this issue is nanostructuration of micron- and submicron-sized particles, which gives the desirable properties associated with nanoparticles (e.g., high surface area and low density) and improved handling properties. In this research, high-surface-area macroporous WO_3 nanoaggregates particles with deposited Pt (Pt/WO_3) were successfully synthesized using flame spray pyrolysis. The macroporous structure was tailored by changing the mass ratio of the polystyrene template to ammonium tungstate pentahydrate. The cavities between the nanoaggregates formed mesopores, which increased the surface area. The high surface area resulting from meso- and macro-pores in the synthesized Pt/WO_3 particles improved their photocatalytic activities in visible-light-induced photodegradation of rhodamine B. The combination of a high surface area and the presence of an in situ-deposited Pt cocatalyst gave a high photodecomposition rate, approximately 9.6 times higher than that achieved with dense WO_3 particles. This research provides a promising strategy for synthesizing submicron particles with high surface areas at a high production rate, and is suitable for industrial applications.

Flame Aerosol Integrated Role-To-Role Lamination Technique for High Performance Battery Fabrication Procedure.

LUTZ MÄDLER, Michael Gockeln, Robert Kun, Suman Pokhrel, *University of Bremen, Faculty of Production Engineering*

$Li_4Ti_5O_{12}$ (LTO) lithium-ion-batteries with high energy density, efficiency and long life time are powerful sources of energy. However, their main drawback is the large scale production cost both in terms of the material designing and the fabrication procedure. Today, the complex and labor-intensive industrial battery fabrication includes coating slurry-based electrodes, assembly and life-cycle test. Hence, to develop next generation innovative battery technology, new synthesis-fabrication procedures are necessary to ensure excellent performance and reduced cost.[1] In our recent work, single and/or double flame aerosol syntheses were utilized to obtain active LTO material and transfer the particles in the dry state on the battery substrate using role-to-role lamination technique.[2] During double flame aerosol combustion, (1) a single individual flame was used to obtain LTO (2) second individual flame was used to obtain carbon.[3] The two aerosol streams were mixed at a certain point above the flame to obtain homogenous C-LTO mixture. For the single flame synthesis, LTO (without carbon) was sprayed on the collecting unit placed at 60 cm above the flame followed by layer transfer either to the standard and/or flexible substrates using role-to-role laminator. The active material and layers were characterized using XRD, BET, and TEM imaging. The carbon content in the active material was determined using thermogravimetric analysis and Raman spectroscopy. The results of the laminated battery electrodes showed enhanced specific discharge capacities compared to reference electrodes prepared using conventional slurry-based doctor blading technique. The variation in lamination pressure was a key to enhanced electrochemical performance. The solvents and/or binder free layer fabrication technique is expected to become economic and promising technique for its use in the flexible and/or non-flexible substrates in the future.

High Throughput Screening of Precursor-Solvent Combinations for Flame Aerosol Chemistry to Design Phase Pure Li4Ti5O12 Energy Storage Materials. SUMAN POKHREL, Florian Meirhofer, Haipeng Li, Johannes Birkenstock, Michael Gockeln, Robert Kun, Lutz Mädler, *University of Bremen, Faculty of Production Engineering*

The industrial development of lithium-ion-batteries based on advanced energy storage materials such as $Li_4Ti_5O_{12}$ (LTO) relies on the phase pure material. Flame aerosol technology for the production of such materials is a key to such synthesis. While the chemistry of the impurity free energy storage material synthesis depends on the choice of precursor-solvent combinations, systematic investigation of lithium and titanium precursors dissolved in five different organic solvents were screened followed by flame aerosol combustion.[1,2] The results of the precursor-solvent screening showed rapid stabilization of humidity sensitive precursors in highly combustible organic acids inhibiting prior TiO_2 precipitation in the solution. The physicochemical properties of aerosol derived particles were extracted using XRD/Rietveld refinements, thermogravimetric analysis, mass spectrometry and vibrational spectroscopy. The results of the LTO particles obtained from the aerosol combustion of highly miscible precursor-solvent combinations with the absence of prior formation of colloidal particles resulted in ultrafine and single crystalline nature with primary particle diameters ranging 4-9 nm. The flame aerosol combustion of less-stable precursor-solvent combinations inducing prior TiO_2 precipitation produced much larger particles and high TiO_2 content reducing LTO phase to as low as 34%. The overall results showed direct relationship between the stabilities of the precursor-solvent chemistry on the nanoparticle properties. To study the energy storage capacity, the pure phase LTO particles were coated on the battery substrates using doctor blading technique. The results of the battery performance showed discharge capacity of 146.5mAh/g for 450 cycles at 1C with the charge retention of 85%, revealing high rate and efficient charge reversibility.

Electrospray Atomization and Deposition of Nanoparticle Suspensions Leading to Nanostructured Porous Coatings.

JOSE L CASTILLO, Santiago Martin, Daniel Rodriguez-Perez, Francisco J Higuera, Pedro L Garcia-Ybarra, *Universidad Nacional de Educacion a Distancia - UNED*

The controlled deposition of aerosols is a valuable tool to prepare thin nanostructured porous coatings as required in many applications. Thus, aerosol nanoparticles can be used as building blocks for materials synthesis leading to thin porous layers with a prescribed morphological structure and still retaining a large surface/volume ratio as distinctive feature. Coatings formed by the accumulation and adhesion of incoming aerosol nanoparticles acquire a morphological structure controlled by the form of the constitutive particles and by the way in which these particles arrive and attach to the forming material. A proper control of the aerosol particle dynamics may lead to granular deposits with a well-prescribed bulk morphology and surface structure.

Experiments have been conducted to prepare nanostructured materials from the steady electrohydrodynamic atomization of liquid suspensions. The electrospray is kept in the cone-jet mode with a Taylor cone at the needle exit and a very thin jet emerging from the cone tip. At some distance away from the cone tip, the jet breaks up into a spray with droplets much smaller that the needle radius, forming a cloud with a narrow distribution of tiny charged droplets. The droplets are driven by the electric field and evaporate along their path leaving a solid residue of charged nanoparticles which are collected on a substrate. The range of parameters leading to a stable cone-jet was studied for two different suspensions; carbon nanoparticles in ethanol and catalytic inks formed by Pt supported on carbon nanoparticles and Nafion® in ethanol.

The morphology of the deposits has been examined by means of digital scanning electron microscope (SEM) images. Upper views of the deposit show a layer structure based on clusters of nanoparticle agglomerates formed by the attachment at the deposit of nanoparticles coming from several electrospray droplets, with the cluster size (of the order of 10 microns) increasing with the flow rate. Lateral SEM images of the deposits cross-sections were processed to calculate the deposit mean density and porosity. The porosity is rather high (always larger than 90%) decreasing as the electrospray flow rate increases.

Coatings prepared from catalytic inks were tested as electrodes in a fuel cell. The performance of the electrodes synthesized using different values of the electrospray flow rate was studied. The electrodes have shown extremely large specific power (reaching a power of 21 kW per gram of Pt in the cell) due to the outstanding properties of the electrosprayed catalytic layer: large porosity, uniform distribution of the catalyst and high density of (Pt) active sites.

These results for fuel cell electrodes show the advantages of the electrospray method in a particular case. But the same methodology could also be used for other applications. The structure of the synthesized material can be tailored according to the application needs to have a given porosity and surface composition. Moreover, layered or composed materials (with a different porosity or different composition on each layer) can be prepared by adequate changes in the control parameters (liquid flow rate and applied voltages in the electrospraying technique) which determine the dynamics of the particles approaching the deposit.

Aerosol Particle Restructuring: Molecular Dynamics of High Aspect Ratio Carbon Nanotubes. NIKOLAOS KATERIS, Adam M Boies, *University of Cambridge*

The Floating Catalyst Continuous Vapour Deposition (FCCVD) process for carbon nanotube (CNT) production is extensively used, but the kinetics within the process are poorly understood. The process involves injection of methane, ferrocene, and thiophene into a hydrogen filled reactor, downstream of which CNT aerogel is continuously drawn. Individual CNTs grow on catalyst nanoparticles, which form after the decomposition of thiophene and ferrocene. The CNTs then collide and form bundles. Further collisions of the bundles lead to the formation of the aerogel. This work aims to explain the mechanism of aerogel formation.

The collision frequency of CNTs has been investigated through stochastic simulations [1]. These simulations allow the calculation of the collision rates of straight and curved CNTs. The specific purpose of this work is the determination of the realignment rate of CNTs and CNT bundles, in order to examine the aerogel formation criteria. This is achieved with a spatially adaptive mesoscale molecular model.

The molecular dynamics after collision are governed by intermolecular van der Waals forces and the time evolution of the molecule arrangement is calculated on LAMMPS. The mesoscale model performs Langevin Dynamics calculations within a simulation box. A bead-spring model is employed to model the axial and bending stiffness of CNTs. Intermolecular forces are modelled using a Lennard-Jones potential, with its parameters scaled according to Markus Buehler's 2006 paper [2], in order to account for the discrete nature of the beads.

It is observed that the bead spacing affects bundling time and using the conventional value of bead spacing equal to CNT diameter is excessively computationally expensive. Therefore, in order to simulate bundling of long CNTs, a mesoscale model of spatially adaptive resolution is developed. This novel approach to bead-spring modelling involves maintaining fine beads in areas where intermolecular forces are dominant and modelling the rest of the molecule with coarse beads. The simulation is regularly paused and the CNT length is repopulated by beads of resolution that provides the necessary accuracy in critical regions.

These modelling techniques enable the calculation of bundling rates of individual CNTs and CNT bundles. For instance, re-alignment time of two individual CNTs is in the order of 1 ns (for lengths of order of 100 nm), whereas their collision time is of the order of up to 100 ns, for a wide range of CNT lengths. Long CNTs and CNT bundles have slower re-alignment rates, which approach collision rates. This re-alignment data is vital for the understanding of the aerogel formation process. Multiple CNTs can also be placed in a simulation box to collide and form bundles, and eventually an aerogel, thus giving information about the critical values that enable aerogelation to occur.

Aerosol Enhancement in the Tropical Tropopause Layer Controlled by Deep Convection, In Situ Production, and Mixing. SHANG LIU, Pengfei Yu, Troy Thornberry, Andrew Rollins, Yuyan Cui, Karen Rosenlof, Ru-Shan Gao, *University of Colorado, Boulder*

Aerosols in the tropical tropopause layer (TTL) are of great interest as the TTL is the main gateway for material transport from the troposphere to the stratosphere. Understanding the abundance and distribution of aerosols in this pristine region is also important for quantification of the anthropogenic influence on climate. However, our knowledge of aerosol properties in the TTL is limited. To bridge this gap, we measured vertically-resolved aerosol size distributions in the TTL over the western Pacific warm pool, an area that features deep tropical convection due to the warm sea surface. The measurements were performed using a custom-built optical particle counter onboard the NASA WB-57F as well as weather balloons based at Guam (13.5º N, 144.8° E) during the NASA POSIDON (Pacific Oxidants, Sulfur, Ice, Dehydration, and cONvection) campaign in October 2016.

From 9 research flights and 1 balloon profile, we find that the vertical distributions of aerosol in the tropical troposphere over Guam can be described by three layers, each with distinct vertical structure and properties. The first layer is from the surface to 5 km, in which the aerosol mass mixing ratio (MMR) decreased logarithmically with height from 2 ppb to 0.08 ppb. The second layer ranges from 5 km to 13.5 km, with the latter coinciding with the typical height of the tropical convective outflow. Aerosol concentrations in this layer are very low, with an average MMR of 0.07 ppb. These observations suggest that aerosols in this layer have been efficiently removed by convection, which serve as an effective aerosol sink by scavenging. The TTL constitutes the third layer, ranging from 13.5 km to 19 km. In the TTL, the aerosol MMR increases linearly with altitude from 0.07 ppb to 1.2 ppb. Good correlation of aerosol MMR with O3 in the TTL indicates that inmixing of the aerosols from the stratosphere may play a role in the rapid increase of aerosol mass. The increase of aerosol MMR could also result from particle growth due to in situ chemical production at the outflow of tropical convections. A global sectional aerosol model coupled with the Community Earth System Model has been used to examine the relative contribution of vertical mixing and local formation of the aerosol mass. In addition, a Lagrangian particle dispersion model (FLEXPART) has been used to identify the source regions of the TTL aerosols and their precursors. In summary, our results demonstrate multiple controls of the tropical deep convection in the life cycle of aerosols, acting as a sink for lower-altitude aerosols and an indirect source of aerosols in the upper troposphere and lower stratosphere.

2RA.2

Physico-chemical Properties of Free Tropospheric Particles at the Remote Pico Mountain Observatory, in the Azores.

CLAUDIO MAZZOLENI, Lynn Mazzoleni, Paulo Fialho, Swarup China, Bo Zhang, Andrea Baccarini, Kaelan Anderson, Simeon Schum, *Michigan Technological University*

To better model the effects of atmospheric particles on climate, it is essential to further our understanding of their lifecycle and their interactions with clouds and radiation; this is particularly critical for understudied remote regions of the atmosphere, such as the marine free troposphere. To this end, we studied the properties of atmospheric particles from the elevated Pico Mountain Observatory (2225 m.a.s.l.), in the Azores, Portugal. The station typically lays above the low marine clouds and samples free tropospheric air masses that are transported over the North Atlantic Ocean from North America or are recirculated from North Africa. For the last several summers, we have measured at the site the atmospheric particle light scattering coefficients using a 3-wavelength nephelometer, the particle concentrations using a two-channel optical particle counter, and the black carbon equivalent mass and iron-containing dust concentrations with a 7-wavelength aethalometer. In addition, we collected samples on different media to study their chemical composition, and the single particle morphology and ice nucleation properties. We used retroplume simulations from the FLEXible PARTicle dispersion model (FLEXPART) to interpret the results based on the air mass origin, transport path, transport time, and source type and region.

We studied the physico-chemical properties of the atmospheric particles, including their optical properties, the detailed bulk chemical composition, and the individual particle morphology and their elemental composition. In this presentation, we will focus in particular on the properties of particles collected during episodes dominated by the transport of mineral dust to the site. Using scanning electron microscopy coupled with energy dispersive X-ray spectroscopy, we performed mineralogical analysis of individual dust particles and studied the heterogeneity of different elements within each particle. These properties are relevant to the particles' interactions with clouds and radiation, especially owing to the location of the atmospheric particles sampled at the station, typically above the marine clouds.

The Birthplace of Cloud Nuclei - A Global Perspective from the Atmospheric Tomography Mission. CHRISTINA WILLIAMSON, Agnieszka Kupc, Anna Hodshire, Jack Kodros, Jeffrey R. Pierce, Pengfei Yu, Karl D. Froyd, Eric Ray, Frank Erdesz, Mathews Richardson, Thaopaul Bui, Charles Brock, *NOAA ESRL and CIRES, University of Colorado Boulder*

Atmospheric aerosols affect climate by direct scattering of solar radiation and by altering cloud properties. Current uncertainties in anthropogenic aerosol forcing are one of the largest factors in total uncertainties in predicting climate change. In situ measurements of the properties, origins and climatic relevance of aerosols are needed to constrain global climate models, validate satellite measurements and better understand aerosol sources and processing in the atmosphere. In-situ measurements of aerosol in the remote free troposphere have hitherto been particularly sparse.

The Atmospheric Tomography Mission (ATom) is a unique set of measurements characterizing the remote free troposphere. ATom uses the NASA DC-8 as a flying lab, equipped with gas phase and aerosol measurements, flying over both Pacific and Atlantic Ocean basins, with near pole-to-pole coverage, constantly scanning between 0.2 and 13km altitude. Measurements are conducted in all four seasons to capture seasonal variations.

We describe the measurement of aerosol size distributions from 3 to 3000nm diameter on ATom, how these measurements inform our understanding new particle formation in the remote atmosphere, and how these particles influence climate. We compare these contiguous global datasets of size distributions ATom with output from two global models with online aerosol microphysics: GEOS-Chem-TOMAS and CESM-CARMA.

2RA.4

Measurements of Black Carbon Concentration and Aerosol Light Absorption during the Finokalia Aerosol Measurement Experiment (FAME-16). ANTONIOS TASOGLOU, Kalliopi Florou, Evangelos Louvaris, Aikaterini Liangou, Georges Saliba, Spyros Pandis, *Carnegie Mellon University*

A month of continuous air monitoring took place at the Finokalia Atmospheric Observatory in Crete, Greece during the summer of 2016. No significant human activities occur within 15 km of the station. The sampled air masses originated from the Balkans, northern Africa and the Mediterranean Sea. This study focused on the measurement of the aerosol light absorption in a remote area characterized by highly oxidized organic aerosol and also high sulfate levels.

In addition to a high-resolution Aerosol Mass Spectrometer (HR-ToF-AMS) and a Scanning Mobility Particle Sizer (SMPS) for size distributions and chemical composition measurements, a suite of instruments for the measurement of the light absorption and the refractory black carbon (rBC) mass concentration was deployed. This included an aethalometer, a photoacoustic extinctiometer (PAX_{405}), a Multi-angle Absorption Photometer (MAAP), and a Single Particle Soot Photometer (SP2).

The fine aerosol mass concentration ranged from 0.3 to 8 $\mu g\ m^{-3}$, with the sulfate and organics accounting for almost 80% of the total mass. The organic aerosol was quite oxidized with an average O:C equal to 0.7. The rBC concentration ranged from 0.04 to 0.3 $\mu g\ m^{-3}$, representing from 2 to 15% of the fine aerosol mass. The measured light absorption was two or more times higher than that of fresh BC. Mie theory was used to evaluate if the effect of the coatings of BC cores by organics and sulfate could explain this absorption enhancement. The role of brown carbon and also other non-BC light-absorbing material was investigated. A thermodenuder was used to link the volatility of the organic aerosol with the observed BC absorption enhancement.

2RA.5

Blowing Snow Influences on Aerosol Composition: Insights from Bulk and Single Particle Measurements in Coastal Antarctica. MICHAEL GIORDANO, Anita Avery, J. Doug Goetz, Lars Kalnajs, Kerri Pratt, Nathaniel May, Alex Lee, Peter DeCarlo, *Drexel University*

In the cryosphere, many open questions regarding aerosol production, processing, transport, and lifetimes still exist. Recent evidence suggests that blowing snow may significantly alter these aerosol processes on both local and regional scales but real-time, on-line evidence is scant. This presentation focuses on both bulk composition changes and single particle results from deploying a suite of instruments, including an aerosol mass spectrometer (AMS), to the Antarctic sea ice during the 2ODIAC campaign, with a focus on blowing snow events. Bulk measurements of the supermicron aerosol and blowing snow samples show that ion ratios are overall consistent with seawater ion ratios, contrary to the submicron ion ratios which show enhancements in sea salt (Na and Cl) concentrations. In the submicron aerosol, these bulk composition changes are shown to be independent from air mass origins. Furthermore, in the snow, no evidence of bromine production is observed indicating that these important reactions are likely occurring in the aerosol scale. Additionally, single particle results from the AMS show a variety of chemical species in addition to sulfates in the submicron aerosol mass. K-means cluster analysis also shows distinct changes in the overall aerosol mass spectra during to blowing snow events.

Arctic Aerosol Sources: Results of PMF on PM10 Collected at Ny Ålesund. GIULIA CALZOLAI, Silvia Nava, Massimo Chiari, Franco Lucarelli, Fabio Giardi, Silvia Becagli, Rita Traversi, Mirko Severi, Laura Caiazzo, David Cappelletti, Stefano Crocchianti, *University of Florence and INFN Florence, Italy*

Ny Ålesund is located on a western fjord of Svalbard Islands, in the northernmost point influenced by the warm West Spitsbergen Current, and thus it is an ideal site for the study of the interaction between the climate change and the atmosphere, ocean and land variations. At the Gruvebadet laboratory, samplings are ongoing since 2010 in the period March to September; in particular, in this work we focus mainly on the results gained by the analysis of daily PM10 samples collected during the 2015 campaign.

Daily PM10 samples were analyzed for the ionic composition by Ion Chromatography (IC) and for metals and rare earth elements (REEs) by Inductively Coupled Plasma - Atomic Emission Spectroscopy (ICP-AES). Further, for the first time, daily samples collected in 2015 were analysed for the elemental composition by Particle Induced X-ray Emission (PIXE) analysis. PIXE is an almost unrivaled technique for the characterization of mineral dust, as it is sensitive to all the crustal elements (except O), including Si, which is usually not accurately quantifiable with other common chemical techniques.

Data on PM10 concentrations and speciation will be shown, for the year 2015 and in comparison with previous years. Further, preliminary data on the 2016 campaign will be also shown: in such year, a new sampling method was set up in order to enhance the sensitivity of the PIXE technique.

Source apportionment was performed by applying the Positive Matrix Factorization (PMF) model. PMF allowed the identification and the quantification of the contributions to the aerosol burden of several sources such as sea salt, ammonia sulfate, biomass burning, mineral dust, nitrate, anthropic/arctic. Contributions vary in the range from few percent (e.g., biogenic emissions) to almost 50% for sea salt. The 2015 campaign was particularly interested by biomass burning transport episodes from Northern America.

The backward trajectories of air masses produced through HYSPLIT software were used to identify regional source areas for the identified PMF factors/sources. This analysis was used to strengthen the interpretation of each factor as a physical source as well as to gain further information on the aerosol long-range transports.

The logistic assistance of the Polar Support Unit of the CNR Department of Earth and Environment (POLARNET) is gratefully acknowledged.

2RA.7

Global Long-range Transport and Lung Cancer Risk of Polycyclic Aromatic Hydrocarbons Shielded by Viscous Secondary Organic Aerosols. MANISHKUMAR SHRIVASTAVA, Sijia Lou, Alla Zelenyuk, Richard Easter, Richard Corley, Brian Thrall, Philip Rasch, Jerome Fast, Staci L. Simonich, Huizhong Shen, Shu Tao, *Pacific Northwest National Laboratory*

Polycyclic aromatic hydrocarbons (PAHs) have toxic impacts on humans and ecosystems. One of the most carcinogenic PAHs, benzo (a) pyrene (BaP), is efficiently partitioned to and transported with atmospheric particles. Laboratory measurements show that adsorbed BaP degrades in a few hours by heterogeneous reaction with ozone, yet field observations indicate BaP persists much longer in the atmosphere, and some previous chemical-transport modeling studies have ignored heterogeneous oxidation of BaP to bring model predictions into better agreement with field observations. We attribute this unexplained discrepancy to the shielding of BaP from oxidation by coatings of viscous organic aerosol (OA). Accounting for this OA viscosity-dependent shielding, which varies with temperature and humidity, in a global climate/chemistry model brings model predictions into much better agreement with BaP measurements, and demonstrates stronger long-range transport, greater deposition fluxes, and substantially elevated lung-cancer risk from PAHs. Model results indicate that the OA coating is more effective in shielding BaP in the mid/high latitudes compared to the tropics because of differences in OA properties (semi-solid when cool/dry vs. liquid-like when warm/humid). Faster chemical degradation of BaP in the tropics leads to higher concentrations of BaP oxidation products over the tropics compared to higher latitudes. This study has profound implications demonstrating that OA strongly modulates the atmospheric persistence of PAHs and their cancer risks.

2RA.8

Adsorption of Trace Atmospheric Gases in Atmospheric Boundary Layer by Dust Aerosol Particles Emitted from Arid Source Areas. BORIS KRASOVITOV, Tov Elperin, Itzhak Katra, Andrew Fominykh, *Ben-Gurion University of the Negev, Israel*

Scavenging of active trace gases by mineral dust storm aerosols is a result of gas adsorption. Adsorption of trace atmospheric gases such as NO_2, SO_2 and HNO_3 by dust aerosol particles contributes to the evolution of concentration distribution of the trace constituents and can affect subsequent chemical reactions in the atmosphere. In this study we suggest a two dimensional model of adsorption of trace atmospheric constituents by mineral particulate matter emitted from area source in a desert. The model is based on the application of theory of turbulent diffusion in the atmospheric boundary layer (ABL) in conjunction with the model of gas adsorption by porous solid particles. The analysis is focused on the local spatial scale (10 km), which is the most important for dust entrainment into the atmosphere. The numerical model is formulated using parametrizations based on the aeolian experiments. Aeolian field experiments were performed at a dust source site (loess soil in Northern Negev, Israel) using a portable boundary layer wind tunnel to determine the emitted PM fluxes for different wind speeds and varying soil conditions. For individual wind-erosion events, wind shear produced turbulence near the surface is responsible for particle entrainment into the atmosphere, while turbulence in the atmospheric boundary layer affects particle diffusion and deposition. Therefore the wind velocity profiles used in the simulations were fitted from our data previously obtained in field measurements conducted in the Northern Negev (Israel) using the experimental wind mast. Size distribution of the emitted dust particles in the numerical simulations was taken into account using a Monte Carlo method. We determined numerically concentration distributions of the particulate matter and trace gas based on the values of shear velocity and emitted dust flux from the soil measured in experiments. Analysis was performed for the meteorological conditions typical for the Northern Negev region. The obtained results demonstrate that using parametrizations based on direct field measurements of wind profile and aeolian erosion has a potential to reduce the uncertainties in atmospheric particulate matter transport and trace gases distribution models and provides a more realistic assessment of dust and trace gases concentration distributions. The model enhances our capacity of quantification of atmospheric dust effects in climate models as well as health risk assessment. The results of the present study can be useful in an analysis of different meteorology-chemistry models including adsorption of trace atmospheric gases by dust aerosol particles emitted from arid source areas.

3AC.1

Not Fade Away: Photolytic Brown Carbon Formation in Aqueous Aerosol. DAVID DE HAAN, Devoun Stewart, Tobin Gramyk, Alexia De Loera, Duncan Ugland, Christian Carmona, Antonio Rojas, *University of San Diego*

Based on results from bulk aqueous phase lab experiments, it is now commonly assumed that brown carbon formed by small, water-soluble aldehydes + ammonium salts are quickly destroyed by sunlight. However, recent cloud chamber studies showing more intense browning with solar simulator lights turned on suggest that this common assumption does not apply to evaporating aqueous aerosol, where brown carbon is more likely to be formed by radical polymerization pathways. Here, we present results of small-chamber and steady-state aerosol experiments where we quantify the amount of brown carbon formed as a function of UV or sunlight exposure and other variables. In deliquesced ammonium sulfate aerosol at 50% RH, we find that 90 min of sunlight destroys brown carbon formed by methylglyoxal + methylamine dark reactions. However, if hydrogen peroxide is added as an OH radical source, more brown carbon is formed in sunlight than in dark reactions (with or without hydrogen peroxide), further evidence of rapid photolytic brown carbon production. We will report on studies of additional chemical systems that form brown carbon, including glyoxal + SO_2.

3AC.2

Enhanced Formation of Brown Carbon Particles at Low Relative Humidity. Masao Gen, Dandan Huang, CHAK K. CHAN, *City University of Hong Kong*

Reactions between dissolved ammonia, $NH_{3(aq)}$, and carbonyls can form light-absorbing species in atmospheric particles. According to previous research, such reactions can be accelerated by actively removing water from the reaction system. Here, we examine the effects of relative humidity (RH) on the reactive uptake of glyoxal (Gly) by aqueous particles of ammonium sulfate (AS), ammonium bisulfate (ABS), sodium sulfate, magnesium sulfate, ammonium nitrate (AN), and sodium nitrate (SN) at RHs of 30, 45, 60, and 75%. In-situ Raman analysis was used to quantify particle-phase Gly via the ν(C-H) peak at 2900-3050 cm^{-1} and a colored product, 2,2'-biimidazole (BI), by its broadband fluorescence as a function of uptake time. The presence of BI was verified by off-line UV-vis and fluorescence characterization, as well as surface-enhanced Raman spectroscopy measurements. Overall, the Gly uptake rate increases with decreasing RH, reflecting the "salting-in" effect, but is suppressed for SN particles at 30% RH, probably due to increased particle viscosity resulting from the formation of Gly oligomers. For $NH_{3(aq)}$-containing particles, the BI formation rate increases significantly with decreasing RH or aerosol liquid water (ALW); however, the BI formation rate is negligible for crystalline AS particles at 30% RH and ABS particles under all RH conditions due to extremely low $NH_{3(aq)}$. Compared to that at 75% RH, the BI formation rate is enhanced by factors of 2.9×10 at 60% RH and 3.3×10^2 at 45% RH for AS particles and 6.5×10 at 60% RH, 2.1×10^2 at 45% RH, and 4.6×10^2 at 30% RH for AN particles. These enhancement factors are much larger than those estimated from increased reactant concentrations due to decreases in RH and ALW alone. We postulate that the reduction in ALW at low RH increases the Gly uptake rate via the "salting-in" effect and the BI formation rate by facilitating dehydration reactions.

3AC.3

Effect of Relative Humidity on Light Absorbing Secondary Organic Aerosol Formation. NETHMI KASTHURIARACHCHI, Alex Lee, *National University of Singapore*

The uptake of water-soluble volatile organic compounds into aqueous aerosol, fog and cloud droplets can result in subsequent aqueous-phase reactions producing secondary organic aerosols (SOA). Glyoxal (Gly), an α-dicarbonyl compound formed by the oxidation of isoprene and aromatic compounds, is extensively studied as a precursor for aqueous SOA. Its reactions with nitrogen containing compounds, both inorganic and organic, have been found to result in the formation of light absorbing aerosols.

Throughout its lifetime, atmospheric aerosols can undergo exposure to different levels of relative humidity (RH). Droplet evaporation at low RH, resulting in a highly concentrated solute environment within the droplet, has been found to accelerate the formation light absorbing compounds. However, studies have shown that the existence of liquid water is highly essential to the production of light absorbing aerosol species, prompting the need for investigating a critical RH level which can effectively facilitate this chemistry.

This study aims to quantitatively describe the effect of RH on the formation of light absorbing aerosols through the reactions of Gly with ammonium sulphate (AS) and Glycine (GL). An initial concentration of 10mM of Gly was mixed with 20mM of AS or 40mM of GL. Each solution was atomized and subsequently dried between 20% and 85% RH. The dried particles were collected on a PTFE filter and extracted with deionised water. Light absorption of aerosol extracts was measured using a UV-vis spectrometer with a liquid waveguide capillary cell. The absorption signals were normalised by the total organic carbon content to obtain the mass absorption coefficient (MAC, m^2/g C) of reaction products observed at different RH levels.

Consistent with previous studies, the Gly-AS system gave a single peak at 287nm while the Gly-GL system gave multiple peaks, with the peak at 380nm being the most prominent. The MAC at the peak wavelengths were plotted against the RH for each system. The MAC of reaction products from the Gly-AS system increased from 100% RH (i.e. bulk solution), reaching a maximum at ∼65% RH. A steady decline of MAC was then observed towards the lower RH. A similar trend was observed for the Gly-GL system with a steady increase of MAC up to ∼55% RH followed by a gradual decline towards the lower RH. Formation of light absorbing aerosol species was insignificant at very low RH condition for both systems. In particular, at ~20% RH, the MAC of reaction products were only comparable to those observed in the bulk solution. Results from both chemical systems highlight the significance of the effect of RH on the production of light absorbing species upon droplet evaporation. The potential influence of phase transition on the formation of light absorbing materials will be discussed.

3AC.4

Marine Organics Alters Sea Spray Physicochemical and Radiative Properties. Aditya Vaishya, JURGITA OVADNEVAITE, Darius Ceburnis, Colin O'Dowd, *National University of Ireland Galway, Ireland*

Nature marine haze layers, predominantly driven by sea spray aerosol, effectively act as mirrors, reflecting back to space part of incoming solar radiation thus modulating global radiation budget. Modulations in the sea spray aerosol physical, chemical, and optical properties on account of enrichment by marine organics may influence the properties, extent, and lifetime of marine haze. Over the North Atlantic waters marine organics constitute significant fraction of the sub micron aerosol population [O'Dowd et al., 2004] during high biological activity (HBA) periods – typically occurring in the months of June, July, and August. Marine air masses, when traversed over the biologically rich North Atlantic waters, bring with them sea spray aerosols enriched with primary marine organics to the coastal measurement station Mace Head (MHD) [O'Connor et al., 2008], on the western periphery of Europe.

We present here the radiative and physicochemical properties of the sea spray aerosols, associated with the low biological activity (LBA) and HBA periods in the North Atlantic, advected to MHD during clean air mass conditions. Aerosol scattering coefficient show a LBA high and HBA low while the spectral scattering exponent shows opposite behaviour. The LBA-high and HBA-low in scattering is found to be driven by contribution of wind-speed generated sea spray aerosols to the marine boundary layer. LBA and HBA scattering values were found be dependent on the square of wind-speed, but LBA scattering values were ~ twice that of HBA scattering values. This apparent difference in LBA-HBA scattering is primarily due to changes in sea spray aerosol chemical composition on account of enrichment by marine organics during HBA periods. Under typical marine boundary layer high humidity fields, sea spray enriched with marine organics are optically less active and their parameterized hygroscopic growth shows a dual state of hygroscopicity flipping from high-hygroscopicity to low-hygroscopicity as the organic volume fraction increases from below ~ 0.55 to above ~ 0.55. The effect of this on Top of Atmosphere (TOA) direct radiative forcing (ΔF) is to reduce the cooling contribution of sea-spray by ~ 5.5 times compared to pure sea-salt spray. Further, using multi-instrument coherent measurement of aerosols properties we show that the LBA-HBA difference in aerosol scattering properties, are not just confined to a change in aerosol chemical composition but also due to change in aerosol dominant size mode, both sub micron and super micron. A shift in dominant aerosol mode to lower sizes, due to organic matter enrichment of sea spray, resulted in increase of aerosol sub micron scattering fraction by over 2.5 times. Combining the effects of changing chemistry and size modes, we show that cooling contribution of sea spray enriched in marine organics is suppressed over 30% under humidity fields associated with cloud base as compare to marine boundary layer humidity fields.

The results presented here highlight a significant coupling between the marine biosphere and the direct radiative budget through alteration of sea-spray chemical composition. The shift to smaller sizes is likely to significant increase the lifetime of the sea spray in the atmosphere, possibly extending the duration and impact of marine haze in the global climate system.

Impact of Springtime Southeast Asia Biomass Burning on a High-mountain Background Station in East Asia: Aerosol Composition and Light Extinction. SHANTANU KUMAR PANI, Neng-Huei Lin, Chung-Te Lee, Ta-Chih Hsiao, Sheng-Hsiang Wang, *National Central University, Taiwan*

Biomass burning (BB) is well-documented as a significant source of aerosols and trace gases in the atmosphere. Emissions from tropical BB impact the physicochemical and optical properties of the atmosphere. BB affects the Earth-atmosphere energy budget by directly scattering and absorbing the incoming solar radiation and also by indirectly modifying the cloud microphysical properties. BB activities in the form of wildland forest fires and agricultural crop burning are very pronounced over peninsular Southeast Asia (PSEA) mainly in spring (late February to April) season. Springtime regional transport of PSEA BB was investigated over downwind locations in East Asia, for example, the Lulin Atmospheric Background Station, Taiwan (LABS, 23.47°N 120.87°E, 2862 m asl), has been an international well-known site for PSEA BB outflow monitoring. As a part of the Seven South East Asian Studies/Biomass-burning Aerosols & Stratocumulus Environment: Lifecycles & Interactions Experiment (7-SEAS/BASELInE) 2013 campaign, the physical, chemical, and optical properties of aerosols were measured at Doi Ang Khang (DAK, 19.93°N, 99.05°E, 1536 m above sea level, asl), an upwind near-source BB location in northern PSEA, where BB activities were densely distributed in the surroundings. The DAK is an excellent site for investigating the characteristics of near-source fresh BB aerosols and their impacts on regional radiative budget, while the LABS is an ideal site to conduct measurements of long-range transported BB. The objective of the present study is two-fold. Firstly, it investigates the detailed BB signature profiles with reference to water soluble inorganic ions, carbonaceous fractions, monosaccharide anhydrides, and low-molecular-weight dicarboxylic acids in $PM_{2.5}$. Secondly, it estimates the impact and role of aerosol chemical composition on light extinction over both locations. This is the first-time attempt of optical closure study at a high-altitude dynamic aerosol environment. BB aerosols are found more water-soluble in the downwind than the near-source location. Organic matter, ammonium sulfate, and ammonium nitrate are found to be the major contributors to the total light extinction, indicating the dominance of scattering type aerosols than over the absorbing type. This study provides needful information to understand the effect of PSEA long-transported BB on the aerosol composition and radiation budget over a remote and free-tropospheric location in East Asia.

3AC.6

Evidence for Pyrazine-Based Chromophores in Cloudwater Mimics Containing Methylglyoxal and Ammonium Sulfate.

LELIA HAWKINS, Hannah G. Welsh, Matthew V. Alexander, *Harvey Mudd College*

Simulating aqueous brown carbon (aqBrC) formation from small molecule amines and aldehydes in cloud water mimics provides insight into potential humic-like substance (HULIS) contributors and their effect on local and global aerosol radiative forcing. Previous work has shown that these (Maillard type) reactions generate products that are chemically, physically, and optically similar to atmospheric HULIS in many significant ways, including in their complexity. Despite numerous characterization studies, attribution of the intense brown color of many aqBrC systems to specific compounds remains incomplete. In this work, we present evidence of novel pyrazine-based chromophores (PBC) in the product mixture of aqueous solutions containing methylglyoxal and ammonium sulfate. PBC observed here include 2,5-dimethyl pyrazine (DMP) and products of methylglyoxal addition to the pyrazine ring. This finding is significant as the literature of Maillard reactions in food chemistry tightly links the formation of pyrazine (and related compounds) to browning in foods. We investigated both the roles of cloud processing (by bulk evaporation) and pH on absorptivity and product distribution in microliter samples to understand the contribution of these PBC to aqBrC properties. In agreement with previous work, we observed elevated absorptivity across the entire UV/visible spectrum following simulated cloud processing as well as higher absorptivity in more basic samples. Absorptivity of the pH 2 sample, following evaporation, exceeded that of the unevaporated pH 9 sample, indicating that cloud processing can overcome the previously observed kinetic barrier imposed on aqBrC formation in acidic conditions. Further, the fraction of pyrazine compounds in the product mixture increased by up to a factor of four in response to drying with a maximum observed contribution of 16% at pH 5. Therefore, cloud processing under more acidic conditions may produce PBC at the expense of imine and imidazole-derived compounds. This finding has implications for further BrC reactivity and degradation pathways.

Co-benefit of Carbon Dioxide and Air Pollutants Emission Reductions by the Air Pollution Prevention and Control Action Plan in the Beijing-Tianjin-Hebei Region of China. ZHENYU LU, Jun Liu, Mindong Chen, Jianlin Hu, *Nanjing University of Information Science & Technology*

Air pollution problems have become very severe in the Beijing-Tianjin-Hebei region of China due to large amount of air pollutant emissions from intensive fossil fuel consumption. Meanwhile, fossil fuel consumption also emits carbon dioxide (CO2) which is a greenhouse gas and causes climate change. Chinese Central Government has set up the Air Pollution Prevention and Control Action Plan, aiming to reduce air pollutant emissions significant through using cleaner energy, industrial upgrading, eliminating high energy consumption industries, and etc. These actions also have potential in reducing CO2 emissions. In this study, we calculate the synergistic effects of the actions in the plan on main air pollutants and carbon dioxide emissions. The objectives include quantitative analysis of the co-benefit from different industries by different measures for different pollutants in the plan.

The Greenhouse gas-Air Pollution Interaction and Synergies model (GAINS) is used in this study. According to each measures in the action plan, new scenarios with modified activities, energy consumptions, the influence of policy, and the equipment levels are generated in the model. The reductions in the air pollutants and CO2 then are simulated for each of the measures. The results indicate that the potential CO2 emission reduction in Beijing and Tianjin from the measures of reducing coal-fired power consumption is 9.2Mt/year and 4.2Mt/year, respectively. In Hebei, the CO2 emission reduction potential of industrial facilities is the largest, up to 122.5Mt/year. Measures for coal combustion power plants in Beijing contribute the most carbon dioxide emission reduction, accounting for 48% of the total CO2 reduction in Beijing. Measures for industries in Tianjin contributes the largest, reaching 42%. Among the main air pollutants the co-benefit carbon dioxide emission reduction is the highest with NOx in Beijing, is the highest with PM2.5 in Tianjin and Hebei.

3CM.2

Aeolian Dust Deposition and Removal on Surrogate Surfaces with Implications in Solar Energy. Benjamin Figgis, BING GUO, Wasim Javed, Said Ahzi, Yves Rémond, *Texas A&M University at Qatar*

In this study, we measured the rates of dust deposition, rebound and resuspension on surfaces exposed in the dusty desert environment of Doha, Qatar, in order to understand the relation between these rates and the environmental variables airborne dust concentration (PM10), wind speed and relative humidity. An outdoor soiling microscopy (OSM) method was used to acquire images of dust particles on collector surfaces at 10-min intervals over 51 days, from which the rate information was extracted. Meteorological and dust data including wind speed, air temperature/humidity and PM10 were also collected in the same period of time. Air friction velocity was determined using scalar wind speed measurements at two elevations. Various empirical models from previous reports were compared against the present experimental results. It was found that the experimental deposition velocity agreed very well with the prediction of an empirical relation based on the experimentally determined air friction velocity (Kim et al. 2000). However, it was difficult to match the experimentally measured resuspension rate and the available quasi-steady-state empirical relations. This difficulty is presumably because resuspension is not steady-state unless in the hypothetical scenario that the deposited dust is steady-state. This study confirms that dust deposition on solar panels can be modelled adequately using existing models, but a better model is needed to adequately describe dust resuspension from soiled surface.

3CM.3

Efficacy Assessment of Vegetative Environmental Buffer in Reducing Particulate Matter Emitted from Poultry Houses.

QI YAO, Zijiang Yang, Hong Li, Michael Buser, John Wanjura, Peter Downey, Chen Zhang, Collin Craige, Alba Torrents, Laura McConnell, Gregory Holt, Cathleen Hapeman, *University of Maryland, College Park*

Particulate Matter (PM) emitted from poultry industry have raised concerns due to the potential negative impacts on residents' health and the neighborhood air quality. In the US, Virginia, Maryland, Delaware and Pennsylvania together constructed a developed broiler belt (areas where chickens outnumber people) along the Chesapeake Bay, containing almost 12% of all broilers in the country. This intense broiler farming has led to increased complains about the degrading air quality in the area. Consequently, Vegetative Environmental Buffer (VEB) has been proposed as a cost-efficient, environmental-friendly remediation practice to the poultry industry. Few studies have been conducted to evaluate the actual efficacy of a functioning VEB in reducing PM emitted from commercial poultry houses. In this study, field experiments were conducted to characterize PM, including total suspended particles (TSP), PM_{10}, and $PM_{2.5}$, emission-concentration profiles, as well as to evaluate the effectiveness of VEB in reducing PM concentrations downstream from the poultry houses equipped with VEB. In addition, a modified small-scale Gaussian Plume air dispersion model was used to estimate PM concentration profiles without a VEB under the same meteorological conditions during the sampling period. The results revealed that the diurnal and nocturnal measured PM emission plume shapes were different, which could due to more stable atmosphere at night. VEB promoted the reduction of PM by 20% to 30% based on the comparison between the measured and model-predicted results, which eliminated the diffusion factor.

3CM.4

Development of Hybrid Dust Collector Installed at the In-use Trains for Removing Aerosols in Underground Subway Tunnels. Sang-Hee Woo, SEUNG-BOK LEE, Jong Bum Kim, Jae-In Lee, Gwi-Nam Bae, Moon Se Hwang, Hwa Hyun Yoon, Hong Ryang Jang, Eunserb An, *Korea Institute of Science and Technology*

Airborne particles, or aerosols in underground subway tunnels are mainly composed of metal compounds (Aarnio et al., 2005; Salma et al., 2007; Martins et al., 2016; Moreno et al., 2017), and they have hazardous health risk of passenger and subway workers (Cheng et al., 2012; Park et al., 2014). Therefore, the air quality in the underground subway tunnels should be improved. Generally, a cleaning vehicle or a ventilation system were used to remove dust on the rail ground during traveling or aerosols at the fixed location in underground tunnels, respectively. However, the cleaning vehicle is very slow to clean whole tunnel, and the ventilation system removes particulate matters only in certain areas. In this study, a hybrid dust collector using both an inertial dust collector and an electrostatic precipitator (ESP) in series for application at the in-use subway trains to remove airborne particles from the underground tunnel. Its field performance test was carried out by attaching it to a real subway train.

Two kinds of hybrid dust collectors have been developed. Model 1 has louver as the inertial dust collector for removing large aerosols and one-stage ESP without a fan, and model 2 has baffle and two-stage ESP with a fan. In both cases, EPS was the main component, and inertial dust collector was added to compensate for the disadvantages of the ESP. The each component of the hybrid dust collectors was optimized by wind tunnel experiments. Based on experimental and simulated results, the hybrid dust collectors were optimized to remove the highest weight of aerosols per hour.

After optimizing, the hybrid dust collectors were installed at the in-use train, and operated for 350 hours for 43 days. As a result, the weight of collected aerosols increased linearly with the operating time. Measured weight of collected aerosols was slightly higher than the prediction value based on wind tunnel experiment result, probably because the aerosol concentration at the bottom of the subway train must be higher than that measured at the height of platform. The hybrid dust collector was able to collect 20 to 40 mg of aerosols per 1 km travel distance, and it captured several hundred grams of aerosols during the field test period.

The Effectiveness of Roadside Vegetation Barriers as a Near-Road Air Pollution Mitigation Strategy: A Comprehensive Evaluation of the Sensitivity to Leaf Area Density. KHALED HASHAD, K. Max Zhang, Pradeep S. Prathibha, Jay R. Turner, Daniel Fleischer, *Cornell University*

Exposure to near-road air pollution is a widespread public health concern due to its association with adverse health effects as demonstrated by several epidemiological and toxicological studies. While emission control technologies and programs to directly reduce traffic-related air pollution emissions (referred to as "active" mitigation) are vital components of air quality management, considerable research has been carried out to identify, develop and evaluate "passive" mitigation strategies to reduce exposure to near-road air pollutants (PM2.5, ultrafine particles (UFP), black carbon, NOx and others). Vegetative barriers have been shown to be a promising passive strategy, but their effectiveness depends on leaf area density (LAD) which is often ill-characterized. In our study, we employ three independent methods to estimate the LAD of an engineered vegetative barrier planted in the front lawn of the Saint Margaret Mary (SMM) school in Louisville, KY. The barrier lies parallel to the road and consists of small shrubs, forbs, and trees selected to maximize pollutant removal but not adversely affect dispersion. The three LAD estimation methods include direct sampling of tree branches, optical porosity measurement and voxel-level analysis from ground-based LiDAR remote sensing data. The derived LAD profiles from each method are used as inputs to a high-fidelity computational fluids dynamics model to quantify the reduction of near-road pollutant concentrations for the SMM site, evaluated against observational data including UFP number concentration collected during intensive field measurements. This study marks the first comprehensive assessment of LAD sensitivity. The preliminary results from our study reveal the need to reduce uncertainties associated with LAD estimations and are being used to optimize planting strategies for Green Heart project which is a neighborhood-scale greening study being conducted in Louisville.

3CM.6

Large Scale PM2.5 Cleaning System for Targeted Area with Several Square Kilometers. SHENG-CHIEH CHEN, Min Tang, Qingfeng Cao, David Y. H. Pui, *University of Minnesota*

The Xi'an 60 m (L) x 45 m (W) x 60 m (H) first generation SALSCS has been successfully evaluated and results showed that it can effectively pull urban polluted air containing high $PM_{2.5}$ into the tower by the nature convective flow created by solar irradiation. The high concentration $PM_{2.5}$ was efficiently removed by well-equipped filter bank before the airflow being released back to the ambient. This first generation SALSCS is intended to be scaled up to create a large quanity of clean air to clean up a large urban area. In the second generation SALSCS, the cleaning mechanism of the filtration was modified to raindrop scavenging, a considered green technique. Theoretical calculations have shown that a higher $PM_{2.5}$ removal efficiency could be achieved by reducing the size of water droplets. However, in practical application a reasonable droplet size should be controlled to around 100 to 500 µm for avoiding their reentrainment into the tower. This second generation SALSCS has 20 m x 20 m x 14 m in size and has been built in Salt City of Jiangsu province, China. Experimental evaluation showed that the $PM_{2.5}$ can be collected with >80% efficiency. The $PM_{2.5}$ laden water will be drained into a collecting pond where the water will be processed to remove the $PM_{2.5}$, and the clean water can be recycled and supplied to the sprayers. This will then provide a low cost and sustainable operation for the SALSCS. To be mentioned that the second generation SALSCS is designed to accommodate the use of solar induced convective flow or electrical powered fan as flow driving force. When the nature convective flow is applied, its size also needs to be enlarged. A third generation SALSCS is being developed for a targeted area in densely populated urban area. It has a reduced size but high clean air delivery with the aid of large array of high powered fan. Besides, a special feature of this SALCSC is that the clean air will directly deliver to ground level, a reverse flow direction then the first and second generation SALSCSs. Theoretical calculations showed that a 20 m x 20 m x 20 m third generation SALSCS can produce clean air of ~1000 m^3/s flow rate with 80% $PM_{2.5}$ removal. It is able to clean up an area of 1 km^2 effectively.

3ED.1

Teaching Practical Aerosol Science in the UK. PAUL WILLIAMS, James Allan, Torsten Tritscher, *University of Manchester and NCAS*

Recently in the UK, we have developed a three day course on aerosol science as a partnership between the University of Manchester, The UK National Centre for Atmospheric Science (NCAS) and TSI Europe. While other well-established courses already exist concerning fundamental theory, this course is focused more on application and practical experience for the benefit of scientists coming into aerosol science for the first time, either as part of work or postgraduate study. So far, this course has been run twice with great success and a third course is planned for 2018. The format is a combination of lectures and practical laboratory sessions. The lectures feature guest speakers covering topics such as aerosol properties and mechanics, size definitions and the theoretical basis of various instruments, with a view to providing the foundations of the mathematical techniques and practical skills that an aerosol instrumentation operator would likely use day-to-day. It also covers various applications for aerosol instrumentation, e.g. within industry. Here we will discuss the material covered and the teaching methods utilized. The practical sessions utilized a pool of equipment belonging to the University of Manchester, NCAS and TSI and provided hands-on experience for the operation and maintenance of various instruments (such as DMAs, OPCs, CPCs and aerosol samplers) and also exercises such as characterising losses down different tubing types and dimensions. The course has proved popular with a mix of different attendees, ranging from PhD students and postdocs, technical staff within the academic sector and those from industry.

3ED.2

Hands-On Aerosol Science and Technology Workshops in the Colorado Front Range. SHANTANU JATHAR, John Volckens, Christian L'Orange, Nicholas Good, David Leith, Sherrie Elzey, Aaron Avenido, Tim Johnson, Andrea Tiwari, *Colorado State University*

Colorado State University (CSU) has recently grown its academic and research programs in air quality, climate and human health with 25 faculty and over 50 researchers across 9 departments conducting research in air quality and/or aerosol technology. To supplement aerosol-related coursework offered at CSU and support graduate training in aerosol research at CSU, we organized a series of three-day intensive workshops for researchers in the Front Range of Colorado in the summers of 2015 and 2016 at the CSU Energy Institute. The goal of these workshops was to provide beginners with a hands-on introduction to aerosol measurement while giving seasoned practitioners an opportunity to review the theory and application of aerosol instrumentation. The 2015 workshop was organized around aerosol size and mass measurement and had ~29 participants. The 2016 workshop was organized around personal aerosol exposure measurement and had ~24 participants. Most of the participants at these workshops were graduate students and researchers from CSU although there were a few outside participants from the University of Wyoming, the National Renewable Energy Laboratory, and University of Colorado Denver.

The first two days of each workshop consisted of three sessions. Each three-hour session included a short theory lecture followed by a demonstration or an exercise. Demonstrations were conducted in small groups of eight to ten people and exercises consisted of a small team of three to five people performing an aerosol measurement. In an example exercise from 2015, teams were introduced to filtration-based particle sampling and were later asked to assemble, calibrate, and deploy a filter train to measure particles in an indoor or outdoor environment at the workshop site. An example demonstration from 2016 was one where mid-priced aerosol monitors (e.g., DustTrak, microAeth, UPAS) were setup in different rooms where an instructor, through hands-on interaction, discussed instrument operation and data acquisition. On the final day of each workshop, TSI Inc. organized a full-day workshop that featured their suite of instrumentation to measure aerosols from combustion sources such as diesel engines, cookstoves, and open burning. The TSI workshop included three modules and followed a similar pattern as the first two days: a short theory lecture followed by a demonstration. The demonstrations were interactive where participants were allowed to vary the source type/mode of combustion fuel, actively operate the instrumentation, and change instrument modes/parameters.

Taken together, these workshops introduced students to a wide array of topics within aerosol science and technology: theoretical background, sampling practices, analytical considerations, instrument selection for various applications, instrument operation, and data analysis. Participant counts and engagement in both years suggest that these workshops provide value to the aerosol research community along the Colorado Front Range. Feedback solicited from the 2015 workshop was used to improve elements of the 2016 workshop. Our goal would be to continue to organize this workshop to support aerosol-related activities at CSU and the Front Range in Colorado in the future.

3ED.3

The Earth's Climate and Human Health Taught through the Lens of Clean Cookstoves. DEBORAH GROSS, Tsegaye Nega, *Carleton College*

Air pollution is a leading cause of death globally, with upwards of 4 million deaths per year caused by indoor air pollution due to cooking with biomass fuels, alone (WHO, 2016). This important problem is intimately connected with such issues as combustion and particle emissions from biomass combustion, the environmental impacts due to gathering the fuel, impacts on the global climate from the emissions of soot, and the impact of social structures on the interaction of people, especially women and children, with smoke from cooking fires. To engage fully with this complex problem requires an interdisciplinary approach that forces students and faculty members to stretch beyond standard disciplinary boundaries. This topic, with specific applications to a clean cookstove program in Ethiopia, has been used successfully at Carleton College to introduce undergraduate students to complex climate and health-related issues, while also providing a fruitful topic for faculty teaching and research collaborations. To-date, this project has been connected to 4 classes in three departments on campus, an off-campus program, and the research programs of two faculty members, and we anticipate that its presence will continue to grow. In addition, a class centered around an international collaboration between students at Carleton College and Addis Ababa University, which also includes components of the cookstove study, has been initiated. In this presentation, the centrality of aerosols, and how they can be connected to a range of topics related to climate and health, attracting students from a variety of disciplines, will be discussed.

3ED.4

Introduction to Aerosols Tutorials. RICHARD FLAGAN, *California Institute of Technology*

A set of two Introduction to Aerosols Tutorials has been presented for many years at AAAR. This paper will give a brief overview.

Tutorial 1 is the first of two that introduce the broad field of aerosol science. We begin with the behavior of individual particles to understand how they behave in the environment, and the physical principles on which most aerosol measurements are based. The drag forces that act on a particle determine its settling velocity and whether it is able to follow the flow of a gas. Several different models describe the drag forces: Stokes law applies for spherical particles moving at modest velocities, though a slip correction must be introduced to account for noncontinuum effects for particles small compared to the mean-free-path of the gas molecules. Other corrections are required if the velocity becomes large enough the fluid inertia affects the motion. Knowledge of these scaling principles makes it possible to relate particle behavior in seemingly disparate systems, and make it possible to determine particle size. The drag forces also determine Brownian motion, and, hence, affect their deposition and losses in the respiratory tract, in sampling systems, and in filters, causing aerosol filtration to be more effective than filtration of particles from liquid media. We will briefly look at how this aerodynamic behavior is employed in determining particle size in a wide range of instruments, including the migration of charged particles in mobility analyzers.

Tutorial 2 continues the basic introduction to aerosol science. In this session we focus on developing the tools to describe the dynamics of aerosol populations. An aerosol is an ensemble of particles in a gas, and the particles are distributed over a range of sizes. Therefore, they must be represented by a particle size distribution. We will discuss the representation of aerosol populations as size distributions, their graphical representation, and models such as the log normal-distribution. Condensation and evaporation of volatile species onto particles determines their growth in the atmosphere, and efficient counting of particles too small to detect optically in condensation particle counters. Both continuum and noncontinuum effects must again be considered, as must the surface tension which governs particle activation, initial activation, and the possibility of nucleating new particles from the vapor phase. These processes also alter the shape of the size distribution. Particle-particle collisions lead to coagulation, which further alters the size distribution. We will examine how these diverse processes are combined to describe the population dynamics for aerosol systems.

3ED.5

Air Quality Board Game: A Cooperative Board Game to Play in Class. SAMARA CARBONE, Guilherme Santa Cecília, Lucas Chiari Couver, Frederico Coelho, Jayder Pereira, Amanda Souza, Felipe Roberto Rodrigues, Felipe Jose Carbone, *Federal University of Uberlândia*

In times when information is widely available and often a reason for distraction, creativity is needed to keep the students interest in class. Ludic learning offers an option into that direction restoring the students' motivation and attention. It is in this context that the Air Quality Board Game (AQBG) was created. The AQBG was adapted from Role-Playing Games (RPG) and consists of a cooperative board game, that is, the students play as a team in order to achieve a goal. Typically in RPG, the players roll dice and let them decide on the success of performing a specific action, such as, to open a door, buy an item or attack an opponent. In the AQBG, the players have to answer questions and to solve problems related to the topic in order to succeed in such actions.

The game was designed to be played by teams from three to six players. In this version, the students may choose among the following characters: the city mayor, environmental city counselor, environmental engineer I, environmental engineer II, meteorologist or the Master, each one has specific skills. The background scenery is a medium sized city (500,000 inhabitants) suffering from air quality degradation and the players are this citizen's last hope!

The board was printed in carton paper and is divided into four districts, which are subdivided into 85 moving zones altogether. The districts are industrial, city center, park and residential neighborhood. In the industrial district there are different industries installed, such as, cement, smelter, food factory, paper and cellulose factory, coal power plant, etc. The teacher decides on the type of industries. The players can move between the districts through the moving zones. The districts emit air pollutants, according to its source type, in the pollution turn. There are special tokens spread over the city (shops, university, city hall and hospital) where the players can buy items, receive advices or heal from the adverse health effects of poor air quality.

The game is played in rounds. Each round is composed of three turns. The first turn is the players' turn. Here each player has three free actions. It is considered an action to move between zones, to purchase items, ask for assistance, use/install/replace instrumentation and implement public policies. The second turn is the pollution turn. That is when the pollutants spread over the city. The pollutants move one zone per round, depending on the atmospheric conditions. In the third turn, new pollutants are emitted to the atmosphere by the polluted zones. Cards containing such information decide the pollutant type (PM, CO, NOx, etc) and the emitted amount.

The main goal is to save the city from air quality degradation before the players die from the adverse health effects. Because at every round there are more pollutants emitted by the specific polluted zones, the players must decide on how to act in order to mitigate the air pollution. Each player spends one life when pollutants reach the national air quality reference levels.

One of the ideas under this methodology is to make it as versatile and adaptable as possible. Thus, it could be used in multiple environments. In addition, different items can be included as cards, and the questions could be adapted to different levels of difficulty on the topic.

The AQBG is still under test and some adjustments are still in course. Special items and skills will be added. A preliminary version of the game was well accepted by the students enrolled in the Air Pollution Control coarse. The students will answer a questionnaire to expose their opinions about playing the game.

3ED.6

McDonnell Academy Energy and Environment Partnership (MAGEEP) Education Network: MAG^{E}Net. BEDIA KARAKOCAK, Tandeep Chadha, Jeff Yang, Orhan Yenigun, Prasad Modak, Pratim Biswas, *Washington University in St Louis*

As a part of McDonnell Academy Energy and Environment Partnership (MAGEEP), McDonnell Academy partner universities are networked and collaborating on various projects related to energy and environment. The consortium of 35 universities and corporate partners work together on energy, environmental, and sustainability research, education, and operations. MAGEEP's mission is to collectively identify and collaboratively tackle important global energy and environmental challenges in an integrated and holistic manner. In addition to the university partnerships, to unite all 35 MAGEEP partners with industry and non-governmental organizations on education, MAGEEP Education Network (MAG^{E}Net) was established in 2015. Each partner university has its own training and degree programs in energy and environment-related areas. The MAG^{E}Net is, however, based on co-utilizing the educational resources and expertise of all faculty at the 35 institutions. An added advantage is in the networking with the corporate sector and developing a model for education with links to industry, government, and non-governmental organizations. An exclusive framework is proposed as a networked approach to establish courses and certificate programs on energy and environment while developing a model for education with links to industry, government, and non-governmental organizations. The overall network will be guided by a MAGEEP educational advisory committee consisting of faculty members from interested institutions. We will demonstrate the use of a CANVAS platform to illustrate how educational modules are set up. Specifically, we will give examples of aerosol modules that have been set up on this platform.

3IA.1

Evaluation of Mobile Air Purifiers under Realistic Conditions. STEFAN SCHUMACHER, Daniel Spiegelhoff, Miriam Küpper, Ute Schneiderwind, Hartmut Finger, Christof Asbach, *Institut für Energie- und Umwelttechnik e.V. (IUTA)*

Over the last years, air pollution has more and more moved into the focus of public attention. This not only concerns the atmospheric pollution, but also the indoor air quality, which can be deteriorated either by infiltration from outside or by indoor sources. Since people in industrial nations spend most of their time inside buildings, the latter is of special importance. A way to improve the indoor air quality are mobile air purifiers, which draw the polluted air through a filter (here a fibrous electret filter) and release the purified air back to the room so that the pollutant concentration decreases exponentially with time.

Different national standards classify the cleaning performance of mobile air purifiers by their clean air delivery rate (CADR), which describes the flow rate of clean air delivered by the air purifier. It is determined by measuring the temporal decay rate of an initial pollution concentration in a closed room while the air purifier is running. Most standards only consider the number concentration of particles larger than 0.3 µm, although relevant indoor aerosols mainly consist of much smaller particles. To address the question whether such CADR measurements yield a praxis-oriented measure, the size-dependent CADR for particles down to 0.03 µm was investigated. It was found that the CADR significantly drops with decreasing particle size, which means that recent standards overestimate the cleaning efficiency with respect to many relevant indoor aerosols.

It is known that the efficiency of electret filters can drastically degrade with time due to exposure to particles, gases, or humidity. Therefore, we developed a method to reproducibly age the filters by burning cigarettes in steps of 12 at the same time in a 25 m^3-room (Finger 2015). Also the aging behaviour strongly depends on the particle size, which can be explained by the size dependence of the electrostatic contribution to the total filtration efficiency (Schumacher 2018). Furthermore, the results were compared to aging with 48 cigarettes at the same time in a 3 m^3-cube as proposed by a recent Chinese standard, which yields a very distinct aging behaviour. This shows that for a praxis-oriented rating of the long-term stability the considered particle size range and the conditions of aging are of great importance.

Standardized tests are always conducted in test chambers without furnishings and with good air mixing. In contrast, in occupied rooms the flow and hence the pollutant dispersion can be much more complex. To investigate possible deviations, an air purifier was operated in an office room with the pristine outdoor aerosol as target pollutant. To measure the local CADR, portable particle monitors based on diffusion charging were located at different positions in the room. At all tested positions they showed similar decay curves, indicating that the cleaned air was homogenously distributed within the room. Also the location of the air purifier did not have a significant influence. However, the CADR determined in the office room was generally slightly smaller than in the standardized test chamber, which might be attributed to the different particle size distribution of the test aerosols.

The IGF project 19145 N was funded via the German Federation of Industrial Research Associations (AiF) within the program to support industrial collective research (IGF) by the German Federal Ministry for Economic Affairs and Energy (BMWi) based on a decision of the German Bundestag.

3IA.2

Measurement of the Fractional Deposition Efficiency of Full Scale HVAC and HEPA Filters for Nanoparticles ≥ 4 nm.

CHRISTOF ASBACH, Tobias Schuldt, Frank Schmidt, Wolfgang Mölter-Siemens, Ana Maria Todea, *IUTA, Duisburg, Germany*

Concerns regarding adverse effects of nanoparticles, e.g. concerning human health upon inhalation, or product quality upon deposition on clean production equipment or the eventual product, such as semiconductor chips, have increasingly been raised over the recent years. Consequently, these particles have to be removed from the supply air for e. g. residential or office buildings or cleanrooms. It is well known from filtration theory that such small particles are efficiently captured in filters because of their high diffusivity. Methods for determining the fractional deposition efficiency are only available and well established for filter media, whereas no such method has existed up to now for full scale HVAC filters. This is mainly due to the lack of suitable particle generators that provide such small particles in sufficient concentrations to test the filters at flow rates of up to several thousand cubic meters per hour. The high efficiency of filters for nanoparticles necessitates very high upstream concentrations in order to still be able to measure the downstream particle size distribution. If the particles are (quasi-) monodisperse, then it would also suffice to only measure the total particle concentration downstream, which can be done even for very low concentrations.

In the present work, we used a flame based nanoparticle generator (FG2, MoTec Konzepte, Bochum, Germany), in which a sodium chloride solution is continuously fed into a hydrogen-oxygen flame, where it evaporates. Upon cooling, the sodium chloride vapor nucleates to produce very small particles at very high concentrations. The so-produced aerosol is mixed with the filtered air in a test rig according to EN 779/ISO 16890 (also comparable to ASHRAE 52.2), in which the test filter is installed. The modal particle diameter can be adjusted between approximately 4 nm and 70 nm via the sodium chloride concentration in the solution, the feed rate of the solution, as well as the residence time of the freshly produced aerosol in the injection system before it mixes with the high flow rate. The generated aerosols are quasi-monodisperse (according to VDI 3491-1) with geometric standard deviations mostly between 1.3 and 1.5 and particle concentrations upstream of the filter in the range of 1e6 1/cm^3 to 1e7 1/cm^3. To extend the tested size range up to 100 nm or to increase the monodispersity of the evaluated NaCl particles, the aerosol particles in the flow sampled from the test rig can be classified with a differential mobility analyzer (DMA) at a fixed voltage. If information on the collection efficiency for particles >100 nm is desired, a DEHS test aerosol can be used. A correction procedure to account for multiply charged particles upon classification with a DMA has been developed and successfully tested. Several new and artificially aged filters ranging from F7 (according to EN 779, comparable with MERV 13 according to ASHRAE 52.2) to H13 (according to EN 1822) have been tested using the newly developed method and set up. The results typically compare well with those obtained from media samples. The experimental set up and test procedure will be presented along with the data from the filter evaluations.

3IA.3

Quantitative Filter Forensics to Assess Indoor Exposures. Raheleh Givehchi, Juan Pedro Maestre, Chenyang Bi, Kerry Kinney, Ying Xu, Dennis Wylie, Sharon Horner, JEFFREY SIEGEL, *University of Toronto*

The aim of this study is to assess the integrated average indoor airborne concentrations of particle-bound contaminants from dust extracted from heating, ventilation, and air conditioning (HVAC) filters by employing a novel quantitative filter forensics (QFF) approach. QFF allows for the estimate of integrated airborne concentrations of concentrations over the duration that the filter was installed and thus has potential to be a useful method to assess indoor airborne exposures. We extracted the dust from HVAC filters in 60 homes located in central Texas, USA. Filters were collected after one month of deployment in both summer and winter. Dust recovered from these filters were characterized for particle-bound contaminants including total fungal and bacterial DNA (using qPCR with generic primers), 36 common fungi species (with qPCR and species-specific primers), endotoxins, and semi-volatile organic compounds (SVOCs). When combined with HVAC system characterizations including system runtime, air flow rate, and filtration efficiency, we calculated the average airborne concentrations of each analyte in the homes in both seasons. The results showed considerable differences between the concentrations of airborne particle-bound contaminants between homes and it is not clear if short-term tests would capture these differences. In general, no statistical differences were observed for concentrations of contaminants between winter and summer. In this sample of homes, the HVAC measurements varied much less between homes than the dust concentration measurements, suggesting that even in the absence of HVAC data analyzing the dust on filters can provide insight about exposures about a relatively homogenous group of buildings. This study confirms the feasibility of the QFF approach to estimate airborne concentrations for a variety of particle-bound contaminants.

3IA.4

Application of the Time-of-Wetness Model to Fungal Growth in Carpet Dust. SARAH HAINES, Karen C. Dannemiller, *Ohio State University*

Microbes in carpet dust represent a major source of human exposure due to resuspension from occupant motion. Our previous work has established that elevated relative humidity in the air is sufficient to support microbial growth in dust. However, typical diurnal variations occur in buildings and it is poorly understood how this may affect growth. The goal of this work was to apply the time-of-wetness model from fungal growth on drywall to model fungal growth in carpet dust. We collected used carpet and dust from 12 homes. We inoculated 10 x 10 cm carpet coupons with dust from the same home and incubated it at 50% equilibrium relative humidity (ERH) and then raised it to either 85% ERH or 100% for 0, 6, 12, 18, or 24 hours per day. Relative growth rates were then calculated using fungal concentration measured by quantitative Polymerase Chain Reaction (qPCR). Results were consistent with the time-of-wetness model, and may have demonstrated activation limited growth. Pearson correlation coefficients for 85% ERH was c 0.898 and for 100% ERH was 0.958. Dominant taxa at elevated ERH were Aspergillus and Penicillium species, among others. Overall, we demonstrate that the time-of-wetness model can be used to model fungal growth in carpet dust.

3IA.5

Measuring Size-Resolved Indoor Particle Concentrations in Single-Family Homes with Asthmatic Residents: A Chicago Field Study. PARHAM AZIMI, Brent Stephens, *Illinois Institute of Technology*

Human exposure to a variety of airborne pollutants such as particulate matter is often greater indoors than outdoors, particularly in residences where people spend most of their time. In fact, indoor exposure to PM2.5 in residences is estimated to account for the vast majority of the chronic disease burden associated with residential indoor air pollution. Moreover, one study recently estimated that residential exposures account for approximately 40% of the childhood and adult asthma prevalence in the U.S., where nearly 8% of the population has been diagnosed with asthma. However, few studies have elucidated the long-term contributions of indoor and outdoor sources to indoor PM concentrations in residences with asthmatic residents. Therefore, the goal of this study is to measure the size-resolved indoor and outdoor concentrations of particles (0.3 to 10 µm using an optical particle counter) in addition to several other pollutants in 45 single-family homes with asthmatic residents in Chicago, IL over a yearlong period. Each home is visited four times per year, with approximately weeklong monitoring periods occurring once per season. Simultaneous measurements of indoor and outdoor particle concentrations will allow for estimating the relative contribution of indoor and outdoor sources by estimating infiltration factors using a censoring algorithm. This work is also part of a larger study to investigate the effectiveness of three common approaches to upgrading residential mechanical ventilation systems in existing homes for reducing indoor pollutants of both indoor and outdoor origin and improving asthma-related health outcomes. These results will be treated as the background measurements before upgrading the mechanical ventilation systems of the participants' homes.

3IA.6

Estimates of Fine and Ultrafine Particle Removal Efficiency for Residential HVAC Filters Using In-Situ Size-Resolved Efficiency Measurements. TORKAN FAZLI, Brent Stephens, *Illinois Institute of Technology*

Central HVAC filters are commonly evaluated for their size-resolved particle removal efficiency by challenging them with a test aerosol in a laboratory setting. However, aerosol classifications that are most commonly used in regulatory monitoring and building measurements typically include integral measures of mass-based concentrations or total number concentrations. Because filter test standards have not traditionally considered these measures, building owners, occupants, and other key personnel cannot make informed decisions on HVAC filtration for these measures. Moreover, because the removal efficiency for integral measures of $PM_{2.5}$ and UFP are also a function of particle size distributions that challenge the filter, one has to consider the varied sources of aerosols found indoors and their size distributions. This work has two objectives: (1) to measure the in-situ size-resolved particle removal efficiency of off-the-shelf residential HVAC filters, and (2) to use these size-resolved efficiency data to estimate integral measures of $PM_{2.5}$ and total UFP removal efficiency for the same filters for typical residential indoor settings based on a survey of indoor particle size distributions. Particle concentration measurements were made upstream and downstream of a wide range of commercial available filters with various minimum efficiency rating values installed in a central air handling unit in an unoccupied residential apartment unit. Next, a literature review was conducted to gather a variety of indoor particle size distributions (PSDs) from across the world and tri-modal lognormal distributions were fit to each of them. Finally, the particle removal efficiency for each filter for integral measures of indoor UFPs and $PM_{2.5}$ were calculated for each indoor PSD. In-situ size-resolved measurements indicate that filters with similar rating values but from different manufacturers can have very different removal efficiencies for $PM_{2.5}$ and total UFPs, and that the assumption for indoor PSDs can greatly impact estimates of removal efficiency.

3IN.1: INVITED

The Role of Ice Nucleating Particles in Convective Aggregation. HASSAN BEYDOUN, Corinna Hoose, *Karlsruhe Institute of Technology*

Deep convection is the primary mechanism by which energy is vertically transported in the tropical atmosphere. This energy transfer, manifested through latent heating by clouds, counteracts top of the atmosphere radiative cooling. Radiative-convective equilibrium (RCE) is a state in which these two modes of energy transfer balance, and has been shown to be a good approximation of the tropical atmosphere.

For over two decades now, numerical simulations of radiative-convective equilibrium at the cloud resolving scale have unraveled a phenomenon termed convective aggregation, whereby deep convection clusters into a single region of the domain. The implication is a polarized atmosphere, in which one region is dry and clear while the other is cloudy and rainy. Cloud ice is a key element in RCE due to the latent heat release of freezing, the radiative warming induced by anvil and cirrus clouds, and ice's role in precipitation formation. Despite ice's contribution to all key modes of the atmosphere's energy exchange within itself and with its boundaries, no study has yet quantified the sensitivity of the RCE state to ice microphysics and subsequently the sensitivity to aerosol perturbations through ice nucleating particles.

We conducted RCE simulations with the ICOsahedral Non-hydrostatic atmosphere large eddy model (ICON-LEM) on a 700km x 700 km domain with periodic boundary conditions, a two moment microphysics scheme, and a fully interactive radiation scheme. Changes made in each simulation were the ice nucleating particle (INP) concentration, the inclusion (or omission) of the secondary ice formation by the Hallet-Mossop mechanism, and the temperature onset for homogenous freezing. Higher INP concentrations exhibited two fingerprints on the microphysical structure: decreased high altitude ice clouds and increased surface precipitation. Both these effects stem from the lower height at which liquid is converted to ice in the high INP configurations. We found a consistent trend in the simulations' effect on the RCE state, whereby configurations which enhanced precipitation led to stronger convective aggregation. This is tied to the increased latent heat flux at the surface and decreased high level cirrus clouds which act to reduce the longwave cooling in the dry regions of the domain. However, the magnitude of these effects is very sensitive to the other ice formation processes of homogenous freezing and secondary ice formation. Increasing (or decreasing) the onset temperature of homogenous freezing can dampen (or amplify) the sensitivity to INPs active at low temperatures while inclusion of the secondary ice formation process has a similar impact of INPs active at high temperatures. The implications of these results on mixed phase clouds, deep convection, and climate will be discussed.

Molecular Perspective on Water Vapor Deposition onto Ice Surfaces. Daniel Schlesinger, Samuel J. Lowe, Xiangrui Kong, TINJA OLENIUS, Jan B. C. Pettersson, Ilona Riipinen, *Stockholm University*

Condensation of water molecules from the vapor phase onto liquid water and ice surfaces plays a crucial role in atmospheric processes. In the present study we focus on the accommodation of water molecules from the vapor phase into the bulk crystalline ice phase. Experimental data suggest that the bulk accommodation coefficient decreases with increasing temperature but data from different experiments are spread over a large range of values indicating large uncertainties (Kong et al., 2014; Skrotzki et al., 2013). The results presented here are obtained combining a refined analysis of recent experimental data with molecular dynamics (MD) simulations. MD simulations are specifically used to investigate the role of the disordered interface of ice in depositional growth processes of the crystal phase.

3IN.3

Sensitivity of Ice Cloud Formation and Precipitation Initiation to Global Distribution and Abundance of Ice Nucleating Particles in E3SM. KAI ZHANG, Xiaohong Liu, Hui Wan, *Pacific Northwest National Laboratory*

Ice nucleating particles (INP) in the atmosphere affect ice cloud formation and can potentially initiate precipitation. However, ice cloud often doesn't appear near regions with largest INP concentrations, because the distribution of supersaturation (that is dependent on water vapor and temperature) and temperature are also important factors. In this study, we evaluated the global distribution and abundance of INP in the Energy Exascale Earth System Model (E3SM) and identified several important regions based on the co-occurrence of INP, supersaturation, and low temperature. We performed simulations with perturbed INP concentrations and investigated the competition between different ice nucleation mechanisms. Impact of spatial variability in vertical velocity and water vapor inside the GCM-grid on ice nucleation is represented in the model using the predicted statistical distribution of updraft velocity and water vapor. Results show the perturbed INP concentrations have various impact on ice cloud formation and precipitation initiation in different regions. The impact on cloud radiative forcing will also be discussed.

Evaluation of Immersion Freezing Properties of Dark-Colored Particles under Mixed-Phase Cloud Conditions. YUTAKA TOBO, Nobuhiro Moteki, Kouji Adachi, Sho Ohata, Atsushi Yoshida, Makoto Koike, Yutaka Kondo, *National Institute of Polar Research*

Dark-colored aerosols are thought to have an influence on the Earth's climate system by heating the atmosphere and by reducing snow albedo. It is well recognized that black carbon (BC) is a major type of dark-colored particles. In addition, recent work has shown that certain amounts of anthropogenic iron oxides having similar color and morphology to BC are present in the atmosphere. Understanding the influence of such dark-colored aerosols on heterogeneous ice nucleation is important to evaluate their impact on ice formation in supercooled clouds and subsequent ice-induced precipitation (i.e., their deposition process to the snow surface); however, their ice nucleating ability remains uncertain and controversial. In this study, we evaluate the roles of different types of dark-colored particles (e.g., BC, iron oxide) as ice nucleating particles (INPs) under conditions relevant to mixed-phase clouds. Immersion freezing experiments using an original cold-stage-based technique (NIPR-CRAFT) indicate that although the particles used here can serve as INPs at temperatures colder than -20°C, their ice nucleating abilities are much lower than those of other types of insoluble particles reported previously. Furthermore, based on field measurements and modeling estimates, we suggest that the contribution of the dark-colored particles to the population of INPs in the atmosphere may be negligibly small, at least in the Arctic region.

3IN.5

The Development and Characterization of a “Store and Create” Microfluidic Device to Study Ice Nucleation Particles.

THOMAS BRUBAKER, Michael Polen, Leif Jahn, Perry Cheng, Vinay Ekambaram, Shelley Anna, Ryan Sullivan, *Carnegie Mellon University*

Characterization of heterogeneous ice nucleation by ice nucleating particles (INPs) is hindered by the analytical challenge of accurately determining the freezing temperature spectrum and atmospheric concentration of these rare one-in-a-million ice nucleating particles (INPs). We have developed a microfluidic device interfaced with our cold plate system with a greatly improved background homogeneous freezing background signal from pure water droplets compared to droplets on a substrate methods. The lower consistent background freezing temperature spectrum enables measurements of weaker but often more abundant INPs that induce freezing near -30 °C, such as found in biomass burning aerosol. We used soft lithography techniques to fabricate our microfluidic device from PDMS. A “store and create” method is used to form and trap an array of uniformly sized droplets. The aqueous droplets have minimal surface interactions with the rigid device since the surfactant-less oil preferentially coats the hydrophobic walls, ensuring the droplets do not contact the polymer surface. Our homogeneous background freezing signal has a median freezing temperature of T_{50}=-33.88± 0.46 °C. The freezing of the droplets was imaged on a gold-plated silicon wafer using reflectance microscopy. An automated script analyzes the images producing the frozen fraction curves and size distribution of our droplets. We characterized our system using SnoMax, illite, Arizona test dust particles, pure water, aged and fresh biomass burning aerosol, and commercially available 100 nm metal oxide nanoparticles. The metal oxide nanoparticle’s near-monodispersed surface properties enable us to begin decoupling different ice nucleation pathways and study INP behavior in a systematic fashion.

3IN.6

Enhancement of the Heterogeneous Ice Nucleation by the Phase State Change of Organic Aerosols. YUE ZHANG, Martin Wolf, Leonid Nichman, Zhenfa Zhang, Avram Gold, John Jayne, Paul Davidovits, Douglas Worsnop, Jason Surratt, Timothy Onasch, Daniel Cziczo, *MIT; Aerodyne Research, Inc.; UNC Chapel Hill*

Cirrus clouds and their effects on earth's radiative balance are major sources of uncertainties in predicting future climate. These clouds also dehydrate air ascending to the tropopause, thereby reducing water content in the stratosphere. However, the formation of cirrus clouds is not well understood. Data from field sites and campaigns have shown that organic aerosols (OAs) dominate the non-refractory aerosols in the free troposphere where ice cirrus clouds typically form. Measurements by aerosol mass spectrometers over forests indicate a high mass fraction of these OAs are derived from the atmospheric oxidation of isoprene and other volatile organic compounds (VOCs). Despite their abundance, the effects of these OAs on ice nucleation (IN) is controversial. Previously, these OAs were assumed to be homogeneously mixed liquids, which limits their IN properties. Recent studies have shown that depending on the ambient humidity and temperature, OAs can exist in semi-solid or solid phase states, which can potentially increase IN activity. This laboratory study systematically examines the effects of aerosol-phase state on IN properties of OAs by using the spectrometer for ice nucleation (SPIN), a commercially available instrument manufactured by Droplet Measurement Technologies, Inc.

Organic aerosols comprised of representative surrogates and the actual components of isoprene photo-oxidation products were generated and passed through a temperature control apparatus, where the temperature of the aerosols can be varied between -25°C and 13°C before entering the SPIN. A scanning mobility particle sizer (SMPS) measured the number-diameter distribution of the particles upstream of the SPIN. An optical particle counter downstream of the SPIN measured the optical signatures of the ice particles and some of the large bare organic particles. The SPIN operating temperature was between -38°C and -46°C. Our results show that pre-cooling the aerosol particles to -25°C enhances the IN onset relative humidity (RH) and the active fraction of IN when compared with non-pre-cooling conditions. Coupled with viscosity and glass transition temperature calculations, we show that the aerosol phase state changes due to the pre-cooling is the reason for this enhancement.

2-Methyltetrol, a multiphase reaction product in the isoprene secondary organic aerosol (SOA) that exist in ambient aerosols, was aerosolized, temperature controlled, and measured by the SPIN. The glass transition temperature of 2-methyltetrol as a function of relative humidity was parametrized based on measurements from dielectric relaxation spectroscopy. Results show that as the viscosity of 2-methyltetrol increases, the IN onset relative humidity decreases (i.e., IN activity increases).

Our study suggests that the phase state of organic aerosols, governed by their chemical composition, affects their IN properties. As the phase state of the organic aerosols changes from liquid to semi-solid or solid, their IN onset relative humidity decreases, sometimes by 10% RH. The isoprene SOA product molecule used in this study suggests isoprene SOAs may be important ice nuclei in the free troposphere.

3MD.1

Improving Single Particle Aerosol Mass Spectrometry (SPAMS) Inhalation Analytics Performance through Rapid Particle Tracking and Sizing. Martin Jetzer, Bradley Morrical, DAVID FERGENSON, Georgios Imanidis, *Novartis Pharma AG*

The two primary challenges in the analysis of inhalational pharmaceuticals and their associated devices (inhalation analytics) are the determination of the aerodynamic particle size distribution (APSD) of the active pharmaceutical ingredients (APIs) and, in the case of combination products, their co-association at the level of the individual aerosol particles. Additional challenges include formulation optimization (via excipient addition or process alteration) and the analysis of device and formulation performance under varying physiological conditions. A unique requirement for any inhalation analytical method is that it must handle a very large load of particles over a very short period of time. Multiple APIs in different combinations and the presence of non-API carrier particles require the composition of individual aerosol particles to be determined, rendering conventional particle counter/sizers substantially ineffective. The preferred method for determining the APSD of orally inhaled pharmaceutical aerosols according to the compendial literature is cascade impaction (for example the Next Generation Impactor, NGI, Copley Scientific, UK) followed by high performance liquid chromatography (HPLC). While highly quantitative for the total concentration of API delivered, this technique does not yield any information regarding the co-associations between the various product components (APIs and excipients) within the formulation. Single Particle Aerosol Mass Spectrometry (SPAMS) was initially applied to inhalation analytics to address this issue.

A SPAMS instrument collects a dual polarity mass spectrum from up to 250 individual particles per second and records the aerodynamic diameter of each particle as well. Unlike predecessor instruments, which froze or returned nonsensical data under heavy particle loads, a SPAMS continues to acquire up to 250 randomly sampled aerosol mass spectra per second under essentially arbitrary aerosol conditions. Because a SPAMS uses a single, square tracking laser that is roughly 1 mm tall, even under very high particle concentrations only a single particle will typically be in the tracking region at a time. The light scatter trace is acquired over a period of ~100 microseconds for each particle so it is also possible to verify that the particle was alone in the mass spectrometer.

However, until now there was no way to estimate the degree of particle load saturation occurring in a SPAMS measurement. Lacking this information, it was necessary to parametrically calibrate SPAMS data versus an NGI/HPLC analysis or a conventional counter/sizer such as a TSI 3321 Aerodynamic Particle Sizer. We have now developed a firmware upgrade to SPAMS, Survey Mode, specifically for inhalation analytics, which is similar to Fast Scatter Mode on the TSI Aerosol Time-of-Flight Mass Spectrometer but with significant additional capabilities. In Survey Mode, a SPAMS observes all aerosol scattering events that occur within the tracking laser over a full second. This allows the SPAMS not only to determine the absolute numbers and the sizes of the particles entering the instrument but also to determine the fraction of the time that any particles are found within the tracking laser, ensuring the integrity of the mass spectra that are acquired in the surrounding times.

We report the analyses of several combination inhalational pharmaceutical products in alternating Survey and mass spectrometric acquisition modes. We observe the progress of the SPAMS from saturation to non-saturation conditions and scale the mass spectrometric data to the total observed aerosol. Simultaneous measurements were made using a TSI 3321 APS to verify the linearity of the SPAMS survey mode. Scaling factors were determined for the SPAMS data, which are expected to be durable across many different aerosol systems.

3MD.2

Directly Measuring the Rapid Evaporation/Growth of Metered Dose Inhaler/Dry Powder Inhaler/Nebulizer Formulations. ALLEN E. HADDRELL, David Lewis, Tanya Church, Jonathan P. Reid, *University of Bristol*

Targeted delivery of pharmaceuticals in the lung could result in less required total dose, lowering exposure time, prevalence of side effects and overall cost. A consensus forum of industrial, academic and regulatory experts identified a poor understanding of the relationships between physicochemical characteristics of drug formulations and performance in the humid environment of the respiratory tract as one key barrier to progress in inhalation therapeutics (a). Thus, quantifying the properties of pharmaceutical aerosol that govern hygroscopic growth will yield the potential for the rational design of new formulations for drug delivery to the lung. The ability to control the hygroscopic growth of inhaled pharmaceutical aerosol to improve drug efficacy through targeted dosing has received renewed interest in recent years.

Broadly speaking, the delivery of an active pharmaceutical ingredient (API) from a starting formulation to the deep lung involves three phases: aerosol generation, transport from the aerosolization device to the mouth, and concludes with inhalation/deposition. The deposition rate in the lung is controlled by the aerodynamic diameter of the droplet at the time of deposition. Thus, the size of the droplet at the point of generation, the reduction in droplet size resulting from the net loss of volatile mass (if present) during transfer from the device to the mouth, and any hygroscopic growth on inhalation will have a dramatic effect on total and regional dose. The interplay between these complex processes are explored here.

The novel aerosol analysis technique for measuring the hygroscopic properties of surrogates of ambient aerosol, the comparative kinetic electrodynamic balance (CK-EDB) was used in this study. Capabilities that are unique/advantageous to the CK-EDB include:

(1) Use of a water droplet to probe the RH of the airflow that the sample droplet is subsequently studied in with accuracy of ±0.1%, an order of magnitude better than conventional RH probes.

(2) Direct measurement of the dynamic behaviour of a droplet of known composition in a static and/or variable environment (resolutions of 50 nm and <100 milliseconds).

(3) Accurate determinations of the radial growth factor, a measure of the equilibrium hygroscopic growth of the aerosol as a function of gas phase RH across a range of RH from dry to >99%, and with temperature ranging from <50C to <-30C. samples.

To be presented are the kinetic and thermodynamic hygroscopic properties of commercially available nebulizer, DPI, and MDI formulations as measured by the CK-EDB.

3MD.3

Biokinetics of Aerosolized Liposomal Ciclosporin a in Human Lung Cells in Vitro Using an Air-Liquid Cell Exposure System (Alice). OTMAR SCHMID, Corinne Jud, Yuki Umehara, Dominik Mueller, Albert Bucholski, Friedrich Gruber, Oliver Denk, Roman Egle, Alke Petri-Fink, Barbara Rothen-Rutishauser, *Helmholtz Zentrum Munchen, Comprehensive Pneumology Center*

Background

Inhalation of drugs in aerosolized form is a promising route for non-invasive targeted drug delivery to the lung. Nanocarrier systems such as liposomes have been explored for inhalation therapy opening new avenues including stabilization of non-soluble drugs (e.g. Ciclosporin A (CsA)) and controlled release. Optimized aerosol delivery technologies are required for implementing aerosols into the early preclinical phases of drug testing (instead of pipetting of substances).

Methods

The previously introduced ALICE (Air-Liquid Interface Cell Exposure) system equipped with an investigational eFlow® Technology vibrating membrane nebulizer has been used for an in vitro study of the biokinetic behavior of nano-sized liposomes loaded with the immunosuppressive drug CsA (L-CsA) at the lung epithelial barrier. Human lung epithelial cells (alveolar A549 and bronchial 16HBE14o- epithelial cells) were exposed to aerosolized L-CsA at the air-liquid interface (ALI) and the temporal profile of the L-CsA dose in the apical, basal and cell compartment were monitored up to 24h.

Results

Aerosolization of different volumes of L-CsA solution with the ALICE resulted in dose-controlled, efficient (ca. 7% of invested substance reached the cells), spatially uniform (<8% SD for different inserts) and reproducible L-CsA (<12% SD) delivery. The measurements were performed under non-toxic conditions as determined by cell viability in pro-inflammatory cellular response at 24h post-exposure. The biokinetics analysis revealed that both cell types formed a tight but imperfect barrier for L-CsA resulting in initially high transbarrier L-CsA transport rates, which ceased after about 4h. This burst-like L-CsA transport profile, which is typically also observed in patients, cannot be observed with standard non-aerosolized (submerged) biokinetics assays. Moreover, a 150-fold higher L-CsA concentration was established in the apical (air-exposed side of the cells) and cell compartment compared to the basal compartment (“blood” exposure side of cells). Most importantly for pulmonary drug targeting, a high cellular L-CsA dose level (20-25% of the delivered dose) was obtained rapidly (<1h) and maintained for at least 24h suggesting rapidly established and uniform drug levels in the lung epithelium.

Conclusions

The ALICE exposure system combined with lung epithelial cells cultured at the ALI offers a reliable and relevant in vitro platform technology to study the effects of inhalable substances such as L-CsA under biomimetic conditions.

3MD.4

Formulation Development and In Vivo Pharmacokinetics of Topotecan for Targeted Treatment of Lung Cancer. PHILIP KUEHL, Michael Burke, Ramesh Chand, Devon Dubose, June Liu, Mathewos Tessema, *Lovelace Biomedical, 2425 Ridgecrest Dr. SE, Albuquerque, NM*

Purpose: Lung cancer remains one of the leading causes of cancer death worldwide with approximately 10% to 15% of lung cancers are of small cell histology. Small cell lung cancer (SCLC) has a very aggressive course, with a median overall survival of about 1 to 2 years with only up to 12% of patients surviving for 5 years after diagnosis even in early stages of the disease. Topotecan (TPT) is a FDA approved chemotherapeutic agent that is active in the treatment of SCLC and is one of the only second-line treatment options. TPT is currently delivered by oral or IV delivery and some patients encounter adverse side effects. Therefore, a novel spray dried powder formulation of TPT has been engineered for inhalation delivery to allow for the direct delivery of this potent compound in a non-obtrusive way and limit systemic exposure. This developed formulation was evaluated in non-clinical rodent pharmacokinetic studies to quantify local drug concentrations at the site of action. The local drug concentrations at the site of action will be used to select dose(s) for non-clinical efficacy models.

Methods: A powder fit for pulmonary delivery through inhalation containing TPT free base was developed and spray-dried on a small-scale custom spray dryer (BLD-35) with 35kg/hr. drying gas capacity from a 100% aqueous solution at 4wt% solids. The solution was adjusted to a pH of 3.5 using HCl to ensure complete dissolution of TPT. Functional excipients, Trehalose and L-leucine, were added for additional stability and particle formation. The developed formulation was characterized for solid state, chemical and aerosol characteristics to confirm its formulation applicability. The formulation was evaluated in a rat nose-only inhalation exposure pharmacokinetic study. The IV dose was 0.7 mg/Kg based on the scaled clinical dose and two inhalation doses of 0.14 and 0.79 mg/kg were delivered. Aerosols were monitored for total aerosol concentration, topotecan aerosol concentration and particle size distribution. Following dosing animals were serially sacrificed for systemic blood and plasma analysis by LCMS. Average concentration versus time profile modeled with non-compartmental analysis.

Results: The final dry powder was 70/20/10 Trehalose/Leucine/TPT (w/w%) and was characterized to be highly respirable free from fusion. The final formulation contained amorphous Trehalose and TPT while also having crystallized leucine character. Testing in a clinical device indicated emitted fractions from a capsule and device was 94.0 ± 3.3 % and the corresponding MMAD, GSD, and FPF (<5 microns) were; 2.9 ± 0.3, 1.9 ± 0.2, and 62.0 ± 1.1 respectively. Topotecan pulmonary deposited doses were 0.13 and 0.79 mg/kg and the IV dose was 0.7 mg/kg. The particle size distribution was measured to be 3.0 µm MMAD. The LCMS analysis showed measurable levels of topotecan throughout almost all time points. The non-compartmental analysis showed a bi-phasic elimination profile from the plasma for IV and inhalation dosing. The inhalation delivery showed increased exposure to the lung tissue for similar doses when compared to IV. The lung tissue exposure approached dose proportionality over the dose range studies. The clearance from the lung was slower following inhalation than IV dose (~ 5 hr. half-life vs 1.2 hr. half-life).

Conclusion: The work presented here demonstrates the feasibility of manufacturing a therapy containing TPT by spray drying. The collected dry powder retained purity, aerosolized in the pulmonary range and was comprised of desirable characteristics by In Vitro assessments. The in vivo PK analysis indicated that when delivered via inhalation and IV topotecan exhibits a bi-phasic elimination profile with increased exposure to the lung tissue following similar dosing IV and inhalation. These results suggest that that with a similar dose the exposure to the lung tissue is increase by a factor of 30. Therefore, inhalation delivery of up to 30-fold lower dose of topotecan than IV could provide similar efficacy for lung cancer and thereby significantly improve toxicity that is greatly limiting the clinical use of this potent anticancer agent.

This study was supported by grant from the NIH/NCI to Drs. Kuehl and Tessema (R01CA193532).

3MD.5

Electrospray Functionalization of Titanium Dioxide Nanoparticles with Transferrin for Photodynamic Cancer Therapy.

NATHAN REED, Ramesh Raliya, Rui Tang, Samuel Achilefu, Pratim Biswas, *Washington University in St. Louis*

Electrospray is commonly used to produce macromolecular ions for mass spectrometry, but it has also been studied for generating monodisperse droplets for the synthesis and self-assembly of nanomaterials [1]. Most recently, electrospray has been used to generate nanoparticle standards [2], fabricate solar cells [3], and deliver nanoparticles non-invasively to the brain [4]. The techniques that enable these applications can be extended to many nanomaterials and can efficiently be used to functionalize nanoparticles in a single step. In this work, we functionalize titanium dioxide (TiO_2) nanoparticles with the protein transferrin (Tf) for application in a novel light-based cancer therapy known as Cerenkov radiation induced therapy (CRIT). Tf is a protein that can target the Tf-receptor which is known to overexpress in many types of cancer. Targeted delivery of the nanoparticles can be achieved by coating the TiO_2 with Tf protein. During CRIT treatment, by co-localizing of the PET tracers with nanophotosensitizers in diseased area, the ultraviolet light (UV) generated from β-decay of the radioisotopes can induce the generation of cytotoxic hydroxyl and superoxide radicals from the photosensitizer TiO_2 nanoparticles in vivo to achieve the therapeutic effect [5].

Using electrospray, we have controllably coated Tf on the surface of TiO_2 nanoparticles by drying monodisperse droplets of Tf and TiO_2 before collection. The coating thickness of Tf was tuned by adjusting the precursor concentration of Tf while keeping the TiO_2 number concentration constant. Scanning mobility particle sizer (SMPS) measurements closely match the expected functionalized nanoparticle size for each Tf concentration. Transmission electron microscope (TEM) images further validate this size data and show monodisperse TiO_2 nanoparticles with a coating of Tf after staining. To validate the function of the Tf is unaffected during electrospray processing, the binding affinity of Tf-coated TiO_2 to the Tf receptor was evaluated via MicroScale Thermophoresis (MST).

Synthesis of Large-Pore Submicron Mesoporous Silica using Salt-Assisted Spray Pyrolysis Method for Controlled Release Drug Delivery. Masoom Shaban, Jalal Poostforooshan, Sarah Reiser, Michael Türk, ALFRED P. WEBER, *TU Clausthal*

Research on mesoporous materials for drug delivery purposes has attracted much attention due to their low cost, non-toxic nature, suitable and adjustable pore diameter, and high specific surface area. However, the irregular bulk morphology of the mesoporous materials obtained by traditional methods is not perfect for drug delivery system. Therefore, to overcome this disadvantage, one strategy is to synthesize submicron mesoporous silica (SMS) with spherical morphology. From a clinical point of view, spherical SMS is widely accepted as the useful drug delivery system, because it can be easily ingested or injected.

In this work, salt-assisted spray pyrolysis was used as a facile aerosol route to obtain large-pore spherical SMS using simple inorganic salts as pore templates and nanocolloidal SiO_2 as building blocks. Significantly, this approach avoids the need for any calcination process and mesoporous particles with high-purity can be produced which is very important in biomedical applications.

The morphology and mesoporous structure of spherical SMS were easily controlled using adjusting salt-to-SiO_2 mole ratio. The textural properties and the topology of the resulting materials were investigated by employing diverse characterization techniques such as scanning mobility particle sizer (SMPS), Micromeretics ASAP 2020, transmission electron microscopy (TEM), and scanning electron microscopy (SEM). Most importantly, porosity was not observed in the particles before exposure to the water, it can be concluded that salt is responsible to induce porosity in the structure. Moreover, wide-angle X-ray diffraction (XRD) and inductively coupled plasma (ICP) results confirmed that there is no residue of salt in the SMS after washing with water.

Then, spray-pyrolysis synthesized spherical SMS was used as a promising carrier for racemic ibuprofen as a poorly water-soluble drug. Ibuprofen is often prescribed to treat e.g. arthritis, fever, and pains, however, its dissolution rate and therewith bioavailability is limited. Therefore, ibuprofen was deposited onto resulting spherical SMS using a controlled particle deposition (CPD) process. This process is a suitable and innovative method for the preparation of dissolution enhancing solid dosage forms without using any additional auxiliary materials.

Finally, it was observed that the ibuprofen loaded-SMS carriers exhibited higher dissolution performances compared to the commercial MCM-41 and SBA-15 type mesoporous silica. Furthermore, the obtained results indicated that there is a direct relationship between specific surface area and obtained drug loading. The SMS carriers with a higher surface area and larger pore volume lead to a higher number of ibuprofen monolayers.

3MS.1

Using Aerosol Photoemission (Ape) for On-Line Process Monitoring of Gas-Phase Particle Modifications.

JANNIS RÖHRBEIN, Alfred Weber, *Clausthal University of Technology*

The surface properties of particulate materials are influencing various powder properties such as flowability, dispersibility, compressibility and general chemical properties like catalytic activity. These characteristics are of significant interest for handling and characterization of those materials. The surfaces of gas-borne particles can be modified in various ways: beside a chemical oxidation, a condensation process might be used to deposit material on their surface. If these condensation processes are to be investigated, it is essential not to change the particle environment during probing.

There are various systems to characterize particle properties such as size, morphology and mass with different degrees between on-line and off-line measurement. However, for the characterization of surface properties of nanoparticles rather involved techniques such as electron spectroscopy (e.g. XPS (X-ray Photoelectron Spectroscopy) or MIES (Metastable Impact Electron Spectroscopy)) have to be employed. These methods suffer from limitations when it comes to (nearly) in situ measurements, i.e. analysis of the particles in the original gas environment, since the electron spectroscopy requires vacuum conditions. When for instance the effect of condensation on the particle surface is to be investigated, vacuum conditions will heavily affect the surface state of the particles due to (partial) evaporation. Additionally, the particle transfer from the synthesis reactor to the vacuum analysing system could lead to sampling artefacts and may be far too complex for process monitoring.

Within this work, a system is presented, which operates at ambient pressure and is based on the photoelectric effect: Singly pre-charged aerosol particles (previously classified by a DMA) are irradiated with light of different wavelengths from an adjustable monochromatic source. The photoelectric effect may remove an electron leading to uncharged particles. Since this method does not require vacuum conditions, the particles can be analysed in the process environment with a simple on-line technique. In addition, in the photoemission measurements morphological effects are taken into account using particles classified according to their mobility with a DMA which is basically given by the particle projection area. Due to the normalization of the photoemission activity to the available surface area the apparatus used here was named Surface-Normalised Aerosol PhotoEmission Sensor (SN-APES).

There already exists extensive, interesting work about Aerosol Photoemission (APE), but the application of APE for process control and monitoring has hardly been addressed. Our approach is the usage of APE for process monitoring of the coating of titanium dioxide with nickel oxide and the diffusion of nickel into the crystal structure of titanium. For this purpose, a commercial photocatalyst (Degussa P25) was dispersed with 1 wt% nickel nitrate in an aqueous solution and spray dried with an atomizer. After drying, the aerosol passed a tube furnace at a temperature representing the process parameter to be investigated. The variation of the product properties with process temperature was analyzed with off-line methods such as TEM, XRD, FTIR and EDX.

By employing aerosol photoemission, it was possible to observe this process on-line, which thereby allows the production of particle material with very defined properties. It was established that the change of the photo-emission behavior of the particles can be related to the surface modification. It turned out that aerosol photoemission, while technically simple, is a very powerful tool for gas phase process monitoring.

3MS.2

Aerosol-assistant Synthesis of Sodium Tungsten Bronze Oxide for UV and IR Shielding. HAO TU, Wei-Ning Wang, Da-Ren Chen, *Virginia Commonwealth University*

The spectrum of solar radiation typically include 10% ultraviolet light (UV), 40% visible light and 50% infrared (IR) light. It is known that UV light is harmful because its high-energy photons can break down the organic bond, potentially resulting in the degradation of matter degradation, eye damage and skin aging. The IR light is the major source of heat radiation. In the summer time, the IR light often raises the temperature in the indoor space when penetrating through windows. The cooling of the indoor space to keep indoor residents comfort consumes much energy. In winters, the indoor heat is partially lost through the IR radiation. Windows with the feature of shielding UV and IR lights while keeping transparent for visible lights have the potential to prevent the residents in the indoor space from the UV radiation while saving energy for cooling the indoor space in summers and heating in winters.

With the properties to absorb the light at in the wavelength less than 370 nm and greater than 800 nm and to be transparent for visible light, sodium tungsten bronze oxide is a perfect functional material for target applications in this study. As a member of tungsten oxides, tungsten bronze oxide is highly resistant to the photochemical corrosion and material degradation and is able to sustain very high temperature, making it suitable for long-term application in hazardous environment. In the literatures, tungsten bronze oxides are synthesized by either hydrothermal, solid reaction or sputtering methods. All of these methods are batched and often require long production time. To the author's knowledge, the above material has not been synthesized by an aerosol route, which is a continuous process to produce materials with high purity and can be easily scaled up in the production.

For the first time, nanoparticles of sodium tungsten bronze oxide were synthesized by an aerosol route in this work. The produced powder of sodium tungsten bronze oxide via the developed aerosol route shows comparable characteristics for the UV and IR light shielding, and the visible light transmittance as the reported one given in literatures. Additionally, a parametric study was also preformed to investigate the effects of the sodium-to-tungsten ratio and operational variables (i.e., the flow rate and heating temperature) on the crystal structure, light absorbance and elemental composition of as-produced powder materials. The details of the developed aerosol route and the result of parametric study will be given in this presentation.

3MS.3

Electric Current-Induced Formation of Defects in Columnar TiO_2 Single Crystals under UV Irradiation for Enhanced CO_2 Photoreduction.

YAO NIE, Pratim Biswas, *Washington University in St. Louis*

Carbon dioxide (CO_2) capture and utilization is a promising potential technology to address global climate change. Photocatalytic conversion of CO_2 into hydrocarbon fuels has attracted abundant research attention in recent years. In this work, columnar titanium dioxide (TiO_2) thin films were synthesized by aerosol chemical vapor deposition (ACVD) method and a new method is reported to generate oxygen vacancies and Ti-related defects (OTDs) in these columnar TiO_2 thin films under UV irradiation with electric current. The defective TiO_2 (TiO_{2-x}) showed a significant enhancement in CO_2 photo-reduction. The substrate, electric current, and electric voltage applied played important roles in affecting the photocatalytic performance. The best performing sample showed the highest CO yield of 375 µmol/g/hr, with an apparent quantum efficiency of 0.045%, which was about 4 times higher than that without current (95 µmol/g/hr), and more than 20 times higher than that of TiO_2 (P25). A recyclability test demonstrated the reversibility of the OTDs in CO_2 photoreduction, with or without an electric current. The formation and healing of OTDs were confirmed by the color change (white to yellow, and back to white) and by HETEM images, UV-vis adsorption, Raman spectra, and XPS spectra. The enhancement of the TiO_{2-x} in CO_2 photoreduction with electric current can be attributed to 1) the narrowed band gap energy, 2) the enhanced chemical adsorption of CO_2, and 3) the better separation of electrons and holes. This study offers new insights into engineering OTDs in TiO_2 for photocatalysis, using an easy and gentle method in ambient environment.

Surface Enhanced Raman Scattering of Silicon Quantum Dots Generated by Laser Ablation. Eisuke Okuchi, TAKAFUMI SETO, Mohamed Abd El-Aal, Makoto Hirasawa, *Kanazawa University*

Silicon quantum dots (Si-QDs, 4 to 12 nm) were fabricated by laser ablation under the helium background gas. Size distribution and the crystallinity of the Si-QDs were controlled by the low pressure differential mobility analyzer (LP-DMA) and the aerosol post annealing process (room temperature to 1273K), respectively. These Si-QDs were deposited on the Cu substrates coated by Ag nanostructure. Raman signal was observed from SiQDs using exciting laser with wavelength of 532nm and power of 0.5 mW with changing the size and annealing temperature (crystal structure) of the Si-QDs. Strongly enhanced Raman signal of Si peak (enhancement factor >10 hold) was observed from the sample prepared by gas phase annealing around the transition temperature of Si crystallization. The enhancement factor decrease with increasing annealing temperature, suggesting a weak interaction between excitation laser (532nm) and nanocrystalline Si (>4nm). The results suggest that the overlapping between the plasmon electric field and the bandgap of Si-QDs might be triggered in the ultrafine silicon nanocrystallines less than 4nm.

3MS.5

Synthesis of Silicon Nanoparticles with Controlled Morphology from Silane Pyrolysis in a Helium Atmosphere and Its Relative Nucleation and Condensation Rates. MIGUEL VAZQUEZ PUFLEAU, Martin Yamane, Pratim Biswas, Elijah Thimsen, *Washington University in St. Louis*

Chemical nucleation is the first step by which gas phase molecules produce solid nanoparticles via chemical reactions. This phenomenon has tremendous technological and environmental relevance, yet, it is still not well understood. Numerous industrial processes including silicon chemical vapor deposition (SiCVD) and silane fluidized bed reactor (SiH4-FBR) are energy intensive processes that could profit significantly from better understanding the initial stages of silicon nanoparticle formation and quantifying the growth rates. However, many difficulties exist to extract experimental kinetic rates in the initial stages of aerosol formation. One of the main challenges is to temporally resolve the kinetics of nucleation and condensation as they occur in the sub millisecond regime. Nevertheless, since the temporal scale of condensation and nucleation are expected to be comparable, the ratio of the speed of both processes can be used to obtain kinetic information.

In this work, a silane pyrolysis flow reactor was used to obtain insights in the nucleation phenomenon. Primary particle size distribution was obtained from transmission electron microscopy (TEM) and supported on X-Ray diffraction (XRD) spectroscopy. These results were contrasted with aerosol online characterizations by scanning mobility particle sizer (SMPS). Interestingly the agglomerate size given by SMPS was not correlated to the reactor temperature but primary particle size distribution was a strong function of it. After finding a suitable temperature where sintering was negligible, primary particle analysis was used to determine the relative condensation and nucleation rates of silane pyrolysis. The results show a relative rate of silicon condensation over nucleation with a dependence to the order of 1.5 with respect to SiH4 precursor. Similarly, the analysis reveals that the total number of formed nuclei is correlated to the initial silane concentration to the power of 2/3. The methodology described here is proposed as a tool to help elucidate the kinetics and morphology of rapidly evolving aerosols made from other materials in a regime where primary particles can be identified and are independent of residence time in the reactor. Such understanding provides experimental information on the nature of the dominant chemical reaction mechanism and can be applied to help engineer silicon nanoparticles for a whole range of applications that require sharp control of primary particle size such as catalysis, battery anodes and biomaterials.

3MS.6

Kinetics of CNT Growth for Aerogelation in FC-CVD Synthesis. FIONA SMAIL, Brian Graves, Adam M Boies, *University of Cambridge*

The potential for macroscopic assemblies of CNTs to create vast improvements in applications where electrical and/or thermal conductivity, low mass, high strength and high toughness are required continues to accelerate research in the field. The most attractive and scalable route to these materials is the one-step continuous synthesis and collection of elastic aerogels of CNTs, using floating-catalyst chemical vapour deposition techniques. The chemistry is driven by an aerosol of iron-based catalyst nanoparticles containing a small amount of sulphur, produced from precursors such as ferrocene (Fe source) and thiophene (S source), which react with hydrocarbon species to grow CNTs.

Recent deconvolution of the process using aerosol sampling techniques has led to new insights relevant to process development, namely:

- The synthesis of long CNTs capable of bundling to form elastic aerogels is driven by the negative slope of the axial parabolic temperature gradient
- The bulk synthesis occurs due to renucleation of Fe-based catalyst particles in the presence of hydrocarbon pyrolysis species
- Renucleation of the Fe-based nanoparticles occurs at higher temperatures and lower Fe supersaturation levels than anticipated as S lowers the Fe nucleation barrier, leading to optimal temperature conditions for CNT growth

To harness the benefits from these recent discoveries for future process scale up, much more information is required about the kinetics of the CNT growth processes in this type of system. While the kinetics of CNT growth in fixed-catalyst bed CVD systems are well characterised, many questions remain about the floating catalyst gas phase synthesis as a) this is a much more difficult system to study b) factors such as diffusion-limitations to growth rates do not apply in the same way. Furthermore, the effect of S, identified since the early days of CNT synthesis as a CNT growth promoted, on the growth rate of CNTs has not been quantified.

This presentation will report the application of aerosol sampling techniques and characterisation of CNT products to the challenge of quantifying CNT growth rates and study how a variety of reaction parameters (catalyst particle size, concentration of S, effect of S-precursor choice, nature of carrier gas, reaction temperature etc) influence the kinetics. The results will aid in optimisation of reactor and process design, to maximise production rates of the macroscopic CNT materials so that their use can be explored and implemented in sectors such as the automotive and aeronautic industries, allowing the benefits of these materials to transform our futures.

3OF.1

Using Oxidation Flow Reactors for Studying the Effect of SOA Aging on Optical Properties and Health Effects. YINON RUDICH, *Weizmann Institute of Science*

Oxidation flow reactors enable studying the effects of aging on various aerosol properties. Here we will present a study on how aging affects the refractive index of non-absorbing SOA under NOx-free conditions. The optical properties of β−pinene and p−xylene SOA produced in an oxidation flow reactor (OFR), were studied using a novel white light-broadband cavity enhanced spectroscopy that measures aerosol extinction as a function of wavelength from 400 to 650 nm. It was found that these SOA are not absorbing in the visible range. The real part of the refractive index (RI), n, for these two types of SOA showed slight spectral dependence. With increased OH exposure, the real part of the refractive index first increased and then decreased, possibly due to an increase in aerosol density and chemical mean polarizability of SOA produced at low OH exposures, and a decrease in mean polarizability of SOA produced at high OH exposures, respectively.

In another study, we investigated the effect of SOA atmospheric aging on cell viability. SOA were formed in an OFR that simulates atmospheric SOA formation and aging dominated by OH radical oxidation under NOx-free conditions. Representative anthropogenic and biogenic volatile organic compounds (naphthalene and α-pinene, respectively) were used. SOA mass and chemical composition were characterized online using a scanning mobility particle sizer (SMPS) and high-resolution time of flight aerosol mass spectrometer (HiRes-Tof-AMS). The SOA were directed to an air liquid interface (ALI) cell exposure system, thus mimicking the deposition of fine particles in the lung. Slightly aged naphthalene-derived SOA (about 2 days) was slightly more toxic than SOA produced from α-pinene. We observed a significant increase in the SOA toxicity following chemical aging for both SOA types, and both aged (10 days) SOA had similar toxicity.

3OF.2

Heterogeneous Oxidation of Brown Carbon Aerosol Diminishes Light Absorption. BENJAMIN SUMLIN, Apoorva Pandey, Michael Walker, Robert Pattison, Brent Williams, Rajan K. Chakrabarty, *Washington University in St. Louis*

Brown carbon (BrC) aerosols are a class of light-absorbing organic aerosols, predominantly emitted from smoldering biomass combustion [1, 2]. BrC aerosols have been shown to absorb near-UV and short visible solar wavelengths which significantly impacts Earth's radiative energy balance. The potential impact of atmospheric processing on the absorptivity of such particles is understudied, and satellite retrieval algorithms and climate models typically treat the optical properties of organic aerosols as constant throughout their atmospheric lifecycle.

Using a Potential Aerosol Mass (PAM) oxidation flow reactor [3], we investigated the effects of photochemical oxidation on the 375-532 nm scattering and absorption characteristics of primary BrC aerosols emitted from smoldering combustion of Alaskan peat, a common fuel for sustained biomass smoldering. Parallel plate activated carbon denuders removed gas phase combustion products, minimizing secondary aerosol formation in the PAM, and a PM_1 cyclone removed particles larger than 1µm. Simultaneous size distribution measurements by a Scanning Mobility Particle Sizer along with a novel Lorenz-Mie theory inversion algorithm [4] facilitated the retrieval of the complex refractive index ($m=n+ik$), and an Aerosol Mass Spectrometer (AMS) was used to obtain the hydrogen-carbon (H:C) and oxygen-carbon (O:C) molar ratios, quantities commonly used to parameterize bulk aerosol composition [5, 6].

Upon oxidation up to approximately 4.5 equivalent atmospheric days, the 375 nm imaginary refractive index and absorption coefficients of BrC particles were found to decrease by ~36% and ~46%, respectively, and the single scattering albedo increased from 0.852±0.005 to 0.898±0.005. From the AMS measurements, we observed an increase in O:C from 0.34±0.01 to 0.40±0.01, suggesting that a transition from functionalization to fragmentation reactions with increasing photooxidation may contribute to the changes in optical behavior. We conclude with simple radiative forcing efficiency calculations that show the effects of atmospheric photooxidation on atmospheric warming attributed to BrC aerosols.

3OF.3

Ultraviolet and Visible Complex Refractive Indices of Secondary Organic Aerosol Produced by Photooxidation of β-pinene and Naphthalene in the Presence of Nitrogen Oxides.

QUANFU HE, Chunlin Li, Yinon Rudich, *Weizmann Institute of Science*

Atmospheric aerosols strongly influence Earth's energy budget by aerosol-radiation interactions and aerosol-cloud interactions. A large fraction of the submicron aerosols in the troposphere consists of organic aerosol components, of which a large portion is secondary organic aerosols (SOA) originated from biogenic and anthropogenic volatile organic compounds (VOCs). However, the optical properties of SOA are still poorly constrained.

The optical properties of SOA can vary as a function of wavelength, and change with SOA chemical composition. In the real ambient, VOCs are typically mixed with anthropogenic pollutants (e.g. nitrogen oxides, NOx). The addition of NOx during SOA formation introduces alternative oxidation mechanisms, thus modifies the SOA chemical composition and potentially changes the SOA optical properties.

In this study, we produced SOA from β−pinene and naphthalene in the presence of NOx with controlled exposure time in an oxidation flow reactor. The chemical composition of the SOA was characterized by a high-resolution time-of-flight aerosol mass spectrometer. Light extinction data in the ultraviolet-visible range (315-650 nm) measured by a broadband cavity enhanced spectroscopy (BBCES) were obtained. Changes in the complex refractive index due to chemical composition evolution caused by different NOx/VOCs ratios will be investigated. Moreover, the influence of photochemical aging on the SOA optical properties for SOA produced in the presence of NOx will be addressed.

3OF.4

Formation and Aging of Secondary Organic Aerosol from Aromatic Compounds. QI CHEN, Yong Jie Li, Xi Cheng, Yan Zheng, Keren Liao, Ying Liu, Tong Zhu, *Peking University*

Oxidation flow reactors have been widely used to study the formation and evolution of secondary organic aerosol (SOA) over time scales ranging from hours to multiple days of equivalent atmospheric exposure. We deployed a Potential Aerosol Mass (PAM) flow reactor in the laboratory to study the formation and oxidative aging of SOA from typical aromatic precursors such as benzene, toluene and naphthalene. NO_x levels in the PAM chamber were controlled by N_2O injection. Gas-phase precursors and oxidation products are detected by using a proton transfer reaction mass spectrometer and a nitrate-ion chemical ionization time-of-flight mass spectrometer. Non-refractory particle components were detected by using a high-performance time-of-flight aerosol mass spectrometer. Data are compared to ambient observations in Beijing. The mass spectra of highly oxygenated molecules (HOMs) produced by the photooxidation of the three types of aromatic precursors cannot resemble the ambient spectra, suggesting that the majority of HOMs may come from other sources in Beijing. Particle-phase organic nitrate contributes greatly to the SOA mass under conditions of high NO_x. The mass fraction of organic nitrate in organic aerosol is highest for toluene SOA and lowest for naphthalene SOA. However, PAM-generated aromatic SOA shows much less N-containing fragments in the spectra compared to urban SOA in Beijing, implying important brown carbon sources other than aromatic oxidation. The elemental ratios of PAM-generated SOA agree well with the previous findings. As the exposure level increases, the atomic oxygen-to-carbon (O/C) ratios of benzene and toluene SOA increase and the hydrogen-to-carbon (H/C) ratios decrease. In contrast, the H/C ratios of SOA generated from naphthalene photooxidation show an opposite trend with aging, suggesting significant fragmentation.

3OF.5

A High Volume Laminar Flow Reactor to Investigate the Influence of Photochemical Aging on the Health-related Properties of Combustion Emission: Method Characterization and Utilization to Investigate Wood Combustion Emissions. OLLI SIPPULA, Petri Tiitta, Mika Ihalainen, Pasi Yli-Pirilä, Anni Hartikainen, Tuukka Ihantola, Pasi Jalava, Ari Leskinen, Jarkko Tissari, Miika Kortelainen, Heikki Suhonen, Ralf Zimmermann, Maija-Riitta Hirvonen, Jorma Jokiniemi, *University of Eastern Finland, Kuopio, Finland*

One of the main challenges for the assessment of the environmental effects of combustion emissions is their constant transformation in the atmosphere, due to photochemical aging, which may change the health-related toxicological, chemical and physical properties of the emission particles. The devices used to simulate aerosol photo-oxidation include smog chambers and different flow tube reactors. The modern air-liquid cell exposure devices used in toxicological studies, with combined physico-chemical characterizations of aerosol emissions, require relatively high amounts of aerosol sample. To provide sufficient sample flow rates of aged aerosols for these studies, a High-Volume Photochemical Emission Aging Reactor (PEAR), capable of photo-oxidizing high emission concentrations and volumes, was designed and constructed. First, the PEAR was characterized and validated with common precursors for inorganic and organic secondary aerosols. Next, the PEAR-method was compared to a smog chamber using emissions of a logwood-fired stove as a reference. Finally, the device was utilized in connection with air-liquid interface exposure systems, providing information on how aging of combustion emissions influences the biological responses of the exposed lung cells.

The reactor is constructed from stainless steel tube which has 254 nm UV lamps assembled at the inner walls. Ozone and water vapor are added into the reactor to produce OH radicals via photolytical decomposition of O_3. The inlet of the reactor consists of flow diffuser, which is designed to achieve a nearly optimal laminar flow profile in the reactor, when used with the designed flow rates (50-200 lpm). The flow dynamics of the reactor were simulated with the aid of computational fluid dynamics software (ANSYS 15.0, Fluent) to optimize the reactor dimensions and other boundary conditions. According to the gas residence times, measured with CO_2 marker gas, almost fully developed laminar flow profile was achieved at a flow rate of 100 lpm. Consequently wall losses of particles < 50 nm in diameter were very low, below 10%.

In the wood stove experiments diluted exhaust from two different spruce log fired stoves were introduced both into the PEAR and in a 29 m^3 smog chamber (Tiitta et al., 2016). The composition and concentrations of gaseous and particulate species were measured online using HR-PTR-ToF (Ionicon) and SP-AMS (Aerodyne), respectively. Aging in flow tube increased the organic aerosol (OA) mass fraction by 2.1–2.7 times the initial OA mass with OH exposures between 0.8–5.8× 10^{11} molec. cm^{-3}s. OA enhancement ratios were at highest with low OH exposures, which corresponded to 1-2 days of equivalent atmospheric aging at typical boundary-layer OH concentrations. In the smog chamber, the wall-loss corrected OA enhancement ratios were 1.8-2.1, with similar OH exposures, indicating slightly more efficient SOA formation in the PEAR. The AMS mass spectra and calculated oxidation state of OA was similar in PEAR and the smog chamber at similar OH exposures. Furthermore, an intermediate slope of Van Krevelen diagram between -0.6 and -0.7 in ambient oxidation levels indicated similar oxidation reactions (e.g. fragmentation and functionalization) in PEAR and in the smog chamber.

To investigate the role of aging on potential health effects of the emissions, A549 cells were exposed to fresh and aged wood combustion aerosol using an air-liquid interface, in which the particle deposition on the cell surfaces occurs via controlled thermophoretic force. Comparison of fresh and aged aerosol indicated higher inflammation (IL-8), and genotoxic (Comet assay) responses for the aged aerosol, while the cell viability and production of reactive oxygen species (ROS) remained at a similar level. Thus, photochemical aging induced clear changes also in the toxicological properties of the emissions.

This work was funded by the Academy of Finland.

3OF.6

Secondary Organic Aerosol Yield, Volatility, and Viscosity from Smog Chamber and Flow Reactor Experiments. WYATT CHAMPION, Sarah Suda Petters, Nicholas Rothfuss, Markus Petters, Andrew Grieshop, *North Carolina State University*

Vapor pressure and viscosity of pure organic compounds are controlled by molecular weight and functional group composition. Secondary organic aerosols (SOA) can be mixtures of thousands of compounds. Although it is not obvious that the pure component relationship applies to complex mixtures, one would expect experimental measures of aerosol yield, volatility, and viscosity to relate to experimental measures of chemical composition. These parameters have substantial uncertainties to which laboratory SOA generation systems contribute. Yield experiments utilizing smog chambers introduce bias due to vapor wall losses, and extended aging is difficult due to relatively low oxidant exposures. Yield experiments with flow reactors utilize high oxidant concentrations that may promote fragmentation reactions as opposed to functionalization (leading to higher volatility products and lower yield) (Bruns et al., 2015), and low residence times that may not allow slower processes to occur (e.g., condensation). Here, we apply a combination of methods to probe the ability of each to give insight into the properties of SOA formed from alpha-pinene (α-pinene), and possibly other well-studied precursors, in several laboratory reactors. Objectives of this study are to: 1) compare volatility and viscosity properties of SOA formed in flow reactors to that produced in 'traditional' chamber experiments, and 2) explore relationships between these fundamental aerosol properties.

Organic aerosol mass concentration and chemical composition are measured using an Aerosol Chemical Speciation Monitor. Flow reactor experiments utilize both pure ozonolysis and oxidation driven by low-pressure UV lamps emitting at 254 and 185 nm (OFR-185) oxidation regimes. Smog chamber ozonolysis experiments are also conducted for the same precursors (e.g., α-pinene, naphthalene). For all systems, aerosol yield is quantified using traditional methods. Additionally, volatility distributions are parametrized with the dual thermodenuder (2TD) approach (Saha et al., 2015) in which varied heating perturbations constrain the thermodynamic (heat of vaporization ΔH_{vap}, and saturation concentration, C*) and kinetic (evaporation coefficient, γ_e) properties dictating aerosol volatility. Temperature and RH dependency of viscosity is inferred from the coalescence time scale of synthesized dimers using two differential mobility analyzers of opposite polarity.

Volatility results from 2TD (25-180°C) experiments indicate a substantial presence (>20%) of very low volatility organics (LVOC) in SOA, and evaporation kinetics consistent with moderate kinetic limitation to evaporation (evaporation coefficient ~ 0.1).

Observations of room-temperature dilution-driven evaporation are consistent with the 2TD-derived volatility parameterizations. These distributions are also consistent with others' observations of higher yields and prevalence of LVOCs via chemical analysis. Coalescence experiment results show that the temperature dependence of dry secondary organic aerosol viscosity is similar to that of coal tar pitch, citric acid, and sorbitol. Glass transition temperatures range from –10 to 20°C. Strong correlations of viscosity with O:C and H:C indicate that viscosity is sensitive to changes in composition.

Relationships between oxidation state, yield, volatility distributions, temperature-dependent aerosol viscosity, and enthalpy of vaporization will be explored for single precursor systems at varying levels of oxidation using an oxidation flow reactor at low and high OH exposures. Similarly, the same relationships are explored across systems from different precursors and using different oxidation methods. This work will ultimately allow for more representative estimates of atmospheric organic aerosols in chemical transport models by providing a more robust representation of physicochemical properties of the particles.

Spatial and Seasonal Variation of Particulate Matter Concentration in Kharagpur-A Mid Sized Town in India. NEHA RANI, B.S Sastry, Kaushik Dey, *Indian Institute Of Technology Kharagpur*

This study represents the spatial and seasonal variation in concentration of particulate matter (PM_{10}, $PM_{2.5}$ and PM_1) of Kharagpur town, India. Kharagpur (220 30' N, 870 72 20' E) is a mid-sized town in Gangetic West Bengal with a population of 207,604. To conduct the study, 32 sites from Kharagpur, were selected and categorized into residential, traffic, commercial and sensitive zone. A one year monitoring has been conducted from October 2014 to September 2015 and a 10 minute data has been taken for each site in every weekend till one year with the help of GRIMM Aerosol spectrometer 1.108. This study gives a detailed account about the annual and seasonal variation of coarse, fine and submicron aerosol concentration throughout the Kharagpur town. The PM data analysis showed that the annual average concentration of PM_{10}, $PM_{2.5}$ and PM_1in study area ranged from 182-365 $\mu g/m^3$, 102-122 $\mu g/m^3$ and 79.81-88.67 $\mu g/m^3$ respectively. The maximum PM10 concentration was found in commercial zone and minimum concentration in sensitive zone. For $PM_{2.5}$ and PM_1, the maximum concentration was observed for traffic zone and minimum was found for residential zone. The seasonal PM data analysis showed highest concentration of PM_{10} (740$\mu g/m^3$) in commercial area and highest concentration of $PM_{2.5}$ (310 $\mu g/m^3$) and PM_1 (237 $\mu g/m^3$) in traffic zone. The PM_{10}, $PM_{2.5}$ and PM_1 concentrations were typically higher during winter season due to prevailing inversion condition causes trapping the pollutants. The significantly high concentration of $PM_{2.5}$ and PM_1 of traffic zone during winter might be the reason of poor dispersion conditions and suspension of fine particles in the ambient air for longer period due to vehicle movement and traffic activities. The submicron fraction of aerosol has been also studied and found that the mean and maximum concentrations of $PM_{2.5}/PM_{10}$ and PM_1/PM_{10} ratios during winter season were slightly higher than summer and monsoon seasons for all the zones. This result also exhibit a condition of poor dispersion and consequently trapping of fine particulates.

3RA.2

Spatial Variation in Aerosol Chemical Composition and Source Contribution in Nepal from Aerosol Mass Spectrometry Measurements. BENJAMIN WERDEN, Michael Giordano, J. Doug Goetz, Khadak Mahata, Narayan Babu Dhital, Nita Khanal, Amit Bhujel, Sagar Adhikari, Siva Praveen Puppala, Maheswar Rupakheti, Prakash Bhave, Robert J. Yokelson, Elizabeth Stone, Arnico Panday, Peter DeCarlo, *Drexel University*

The Kathmandu Valley, an urbanized basin in Nepal, is home to over 3 Million people, and is one of the fastest growing metropolitan areas in South Asia. It is subject to extreme pollution events due to numerous unmitigated localized pollution sources and regional transport from the Indo-Gangetic Plain (IGP). Over 10% of Nepali fatalities are from lung disorders, making it the most common cause of death in the country. Previous field work has studied gas species, wintertime VOCs and PM in the valley. The Nepal Ambient Measurement and Source Testing Experiment [NAMaSTE] of 2015 is the first deployment of a High-Resolution Particle Time of Flight Aerosol Mass Spectrometer (HR-PToF-AMS) in Nepal. Recent measurements in 2017-2018 provide context for spatial analysis of aerosol composition differences and their source contributions in the Kathmandu Valley and Nepal.

The in-situ ambient measurements were made at the Bode site in NAMaSTE 2015. This location is just to the east of Kathmandu. Measurements made in April 2015 were cut short by the 2015 Gorka earthquake so follow-up measurements to complete the dataset were performed in winter of 2017-2018. The winter measurements were made at several other locations in the Kathmandu Valley, and in Lumbini, Nepal in the Indo-Gangetic plain. Differences in aerosol loading and composition are related to the differences in sources and prevailing meteorology at the various sites. Additional gas phase (CO, CO_2, CH_4, H_2O, O_3, NO_x, SO_2,) and particle phase (BC, total PM, filters) measurements were taken in addition to the AMS data and are used to interpret the AMS dataset. Positive Matrix Factorization was used to identify aerosol sources, and chemical signatures were compared to source measurements made during NAMASTE 2015.

The mean concentration of $PM_{2.5}$ in Bode, April 2015 was 83 ± 45 $\mu g/m^3$, which is above the 24 hour WHO exposure threshold of 25 $\mu g/m^3$ and annual continuous exposure limit of 10 $\mu g/m^3$. AMS species show a clear diurnal pattern, with extremely elevated concentrations in the morning. Daily concentration patterns are driven by westerly winds in the late morning to afternoon. This wind is the main method of ventilation, however, it can also introduce pollutants formed over the IGP. Overnight there is confinement by the boundary layer and stagnation due to temperature inversions. This causes an increase in secondary aerosols from an abundance of ammonium, nitrate, and chlorides.

Supplemental AMS measurements at in the southeastern edge of the Kathmandu Valley (Dhulikhel) suggest a strong adabatic/katabatic flow pattern driven by solar gain. The central Kathmandu site, Ratnapark, is heavily influenced by traffic in the city center, with dramatic increases in aerosol loading observed during peak traffic times. Measurements outside of the valley in the IGP (Lumbini) show heavy loading of organics, NH_4, and non-refractory chloride in winter fog episodes.

Localized sources of anthropogenic emissions such as traffic, garbage burning, brick kilns, solid fuel, and dung burning for cooking and agriculture are likely sources of elevated pollutant emissions. Burning of trash and biomass coupled with motor vehicle emissions are a major source of aerosol loading in the measurement region.

3RA.3

Observation of New Particle Formation and Growth for Rural Southwestern New York State. JOSEPH P. MARTO, James Schwab, Fangqun Yu, Gan Luo, *University at Albany, SUNY*

New particle formation (NPF) and growth events are known to introduce significant numbers of particles into the atmosphere which have implications for public health, climate, and atmospheric chemistry. A Fast Mobility Particle Sizer (FMPS) and an Aerodynamic Particle Sizer (APS) continuously measured particle size distributions from 6nm to 20µm to detect changes in particle number and size distribution at Pinnacle State Park (PSP) in rural southwest New York state (42°05′42″N 77°12′54″W) for a year starting March 2017. These measurements indicate dozens of NPF events in a variety of meteorological conditions with most events occurring in the Spring and Fall, and fewer in Winter with a minimal number of events during the Summer. The particle data is combined with collocated measurements of meteorological parameters and numerous gaseous and aerosol properties in an effort to better understand the trigger mechanism and dynamics of nucleation and growth events. Data from the 2017 campaign was compared with observations from briefer field intensives in Summer 2004 and Spring 2009, and a six-month observation period in 2012 to assess any changes in NPF events, specifically in relation to changes in concentrations of chemical precursors. Observational results were also compared to results from a GEOS-Chem model with size-resolved advanced particle microphysics to better interpret the specific chemical and meteorological conditions during these events.

3RA.4

Understanding the High-Resolution Size Distribution of Organic Species over the Indo-Gangetic Plain. NAVANEETH M. THAMBAN, S.N. Tripathi, Bhuvana Joshi, Donna Sueper, Manjula Canagaratna, *IIT Kanpur*

Detailed understanding of the size distribution of organic species in Indo-Gangetic Plain (IGP) at winter period is very important due to their complexity in origin and atmospheric processing. High-Resolution Particle Time of Flight (HR-PToF) size distribution analysis was performed on the High-Resolution Time of Flight Aerosol Mass Spectrometer (HR-ToF-AMS) derived organics data to identify the size distribution of various organic proxies and their relative modes. HR-PToF size distributions of Unit Mass Resolution (UMR) organic proxies (SVOOA, COA and, HOA) show a distinct mode of primary and secondary organic families. The relative abundance of this primary (CH) and secondary (CHO) organic families in a specific UMR proxy can influence its size distribution mode in UMR analysis. The diurnal variation of the mid-modal diameter indicates that the HOA, COA, BBOA are showing a diurnal growth (increase in the mid modal diameter) during the daytime, where, the highly oxygenated LVOOA shows no increase in its mid-modal diameter throughout the day.

3RA.5

Aerosol Characteristics during Intense Crop Residue Burning: A Case Study Over Indo-Gangetic Plain. NANDITA SINGH, Vishnu Murari, Rajesh Kumar Mall, R.S. Singh, Tirthankar Banerjee, *Institute of Environment and Sustainable Development, BHU*

The Indo-Gangetic Plain (IGP), South Asia experiences frequent haze events during post-monsoon (October-November), especially influenced by burning of agricultural residues over upper IGP, and additionally instigate by regional boundary conditions. To understand the effects of biomass burning on regional aerosol characteristics, size-segregated airborne particulates were collected in Varanasi during October to November 2016. Aerosol samples were analyzed for both biomass burning tracers (levoglucosan, K^+, and NH_4^+) and water-soluble ions in coarse mode ($PM_{>2.1}$), finer mode ($PM_{1.1-2.1}$) and accumulation mode (PM<1.1). The concentration of fine particles ($PM_{2.1}$) was found to continuously increase during the period ($PM_{2.1}/PM_{>2.1}$: 0.2-1.5), while fine particles especially dominated during later phase. Biomass burning tracers like levoglucosan were found highest in accumulation mode, followed by fine and coarse mode, and temporal analysis showed the gradual increasing trend similar to particle ratio. The secondary inorganic ions (NH_4^+, NO_3^- and SO_4^{2-}) constituted the major proportion of water-soluble ions and were found highest in $PM_{<1.1}$. A positive correlation was also noted between levoglucosan with K^+ (0.86) and NH_4^+ (0.93) for $PM_{<1.1}$ referring common emission sources. The significant change in fine-mode particle concentration, biomass burning tracers, and secondary inorganic ions in accumulation mode indicate the influence of biomass-burning on fine-mode particulates. MODIS fire count and air-mass back trajectories also indicate possible advection pathways of aerosol from upper to lower Gangetic plain.

Keywords: Levoglucosan, Indo-Gangetic Plain, Biomass-burning, Accumulation mode

3RA.6

One Year Vertically Resolved Optical Closure Study of Aerosol Properties at a Meteorological Tower in Western Europe. Julia Perim Faria, ULRICH BUNDKE, Sebastian H. Schmitt, Thomas F. Mentel, Timothy Onasch, Andrew Freedman, Astrid Kiendler-Scharr, Andreas Petzold, *Forschungszentrum Jülich*

The way airborne aerosols impact climate, either by scattering light or by absorbing it, is well known and documented. The overall effect on the radiation budget depends on three main aerosol characteristics: optical depth, single scattering albedo and backscatter fraction (Haywood and Shine, 1995). Although the aerosol and light interaction mechanism is well understood, the quantification of the fore mentioned impact still presents major uncertainties.

In 2015 a new technology was introduced for measuring single-scattering albedo using a single equipment, the Cavity Attenuated Phase Shift Single Scattering Albedo Monitor (CAPS PMssa), developed by Aerodyne Inc. (Onasch et al., 2015). The instrument, operated in the red spectrum (630nm) has been previously assessed in a multi-instrument optical closure study in the laboratory using controlled particle generation systems and known particle compositions (Faria et al., 2016). The results obtained showed an excellent agreement with proven technology for both absorption and scattering measurement.

Following the laboratory study, the instrument set-up was taken, to a filed campaign, in August 2016, where it sampled ambient air from three different heights, 10, 50, and 120m through sampling lines strategically installed at a meteorological tower located in Jülich, Germany. The instruments used in this campaign are:

- CAPS PMSSA (Aerodyne): Extinction and Scattering Coefficient (630 nm)
- CAPS PMSSA (Aerodyne): Extinction and Scattering Coefficient (450 nm)
- Aurora 4000 (EcoTech): Scattering Coefficient (635, 525 and 450nm)
- PSAP (Radiance Research): Absorption Coefficient (660, 530 and 467nm)
- TAP (Brechtel): Absorption Coefficient (652, 528 and 467nm)
- CPC (GRIMM): Particle Number
- OPC (GRIMM): Particle Size Distribution (655nm)
- AMS (Aerodyne): Chemical Composition.

As the results obtained for the laboratory study, the multi-instrumental optical closure study result during the long term ambient air measuring campaign also showed a good agreement. A few differences were spotted and have been deeper studied, as the Ångstrom exponent from the TAP and PSAP instruments. Regarding the CAPS PMSSA, we have observed that the scattering channel is not stable enough for a long term deployment and needs to be improved.

The chemical information was also analysed by using the data acquired by the AMS system and by the study of the Ångstrom exponent obtained from the multi-wavelength instruments.

The results obtained over the 1 years monitoring campaign have shown many interesting aspects such as the atmospheric aerosol stratification over specific meteorological conditions. It was also possible to observe seasonal trends on aerosol characteristics, such as optical and chemical parameters, size, and load, including vertical distribution.

A few interesting punctual cases were selected to be studied, as the forest fires that occurred in the Iberian Peninsula in October 2017. During week 42, higher extinction, scattering and absorption coefficients were observed. The absorption Ångstrom Exponent average was reduced from 1.52 ± 0.1647, the period before and after week 42, to 1.47 ± 0.1158 during fire period, as expected. This has also been detected and measured by the remote sensing station located in Jülich (JOYCE - Jülich Observatory for Cloud Evolution, Löhnert et al. (2015)).

Heterogeneous Reaction of Isoprene and Ozone on α-Al2O3 Particles Using Micro-FTIR Spectroscopy. Hongyang Lian, Pang Shufeng, YUNHONG ZHANG, *Beijing Institute of Technology*

Isoprene, a volatile organic compound (VOC), is mainly emitted from biogenic sources with global emissions of about 500 Tg yr-1. Though secondary organic aerosol (SOA) from isoprene ozonolysis through the gas-phase or aqueous reaction has been reported, the research on the heterogeneous reaction of isoprene is lack. As one of the typical oxide minerals, alumina contributes about 15% by mass to the total dust burden in the atmosphere, which has a defined chemical composition and is widely used as model minerals for studying heterogeneous reactions. In order to assess the impact of isoprene ozonolysis on the global SOA budget, it is important to understand heterogeneous reaction of isoprene ozonolysis on the mineral particles and SOA the formation.

The heterogeneous reactions of α-Al2O3 particles with the mixture of ozone (~60 ppm) and isoprene (~50 ppm) were studied as a function of relative humilities (RHs). The reactions were followed in real time using microscopic Fourier transform infrared (micro-FTIR) spectrometer to obtain kinetic data. The results show that ozone leads to rapid conversion from isoprene to carboxylate (COO-) on the surface of α-Al2O3 particles in initial stage. The amount of carboxylate ions on the sample was determined by the infrared absorption calibration curve in order to quantify the carboxylate ions formation rate d[COO-]/dt in terms of the reactive uptake coefficient. The reaction is sensitive to RHs and surrounding water significantly suppresses the formation of the carboxylate ions. For the isoprene ozonolysis reaction on the α-Al2O3 particles, the reactive uptake coefficient is strongly enhanced by over a factor of four as the RH decreases from 87% to 28%. The results imply that the Criegee intermediates generated from isoprene ozonolysis have low reactivity toward water resulting in the suppression of SOA formation.

4AC.2

Methylthreonic, Methylerythronic, and Methyltartaric acids: Highly Oxygenated Markers for Isoprene Secondary Organic Aerosol Aging. MOHAMMED JAOUI, Rafal Szmigielski, Nestorowicz Klara, A. Kolodziejczyk, K.J. Rudziński, W. Danikiewicz, Michael Lewandowski, Tad Kleindienst, *EPA/ORD/NERL*

We investigate the formation of new highly oxygenated molecules (HOMs) associated with secondary organic aerosol (SOA) originated from isoprene photooxidation and ozonolysis under a wide range of conditions. SOA was generated by the oxidation of isoprene/air mixtures in the presence of NOx, H2O2, methyl nitrite, or ozone. The effect of relative humidity, acidity, and OH radical scavengers (ozonolysis experiments) on the formation of these HOMs was investigated. Using a detailed analysis of mass spectra obtained from GC-MS of silylated derivatives in EI and CI modes, and UPLC/ESI/QTOF HRMS, and collision-induced dissociation in positive and negative modes, we identified not only typical isoprene products, but also six HOMs: 2-methylerythronic acid (2MeTrA), 3-methylerythronic acid (3MeTrA), 2-methylthreonic acid (2MTrA), 3-methylthreonic acid (3MTrA), L-methyltartaric acid (L-MTA), and D-methyltartaric acid (D-MTA). We confirmed their structure by synthesizing them in our laboratory. Isoprene HOMs with O/C ratio of 1 and 1.2 were not detected in the presence of OH scavenger during ozonolysis, suggesting OH radicals are important in isoprene HOMs formation. The presence of these HOMs in the gas and particle phase simultaneously provides evidence of their gas/particle partitioning. The occurrence of these HOMs in ambient aerosol collected during the past 15 years in several locations in USA and Europe provide direct molecular evidence of isoprene aging processes in ambient aerosol. For example, the average concentrations of 2MeTrA + 2MTrA, 3MeTrA + 3MTrA, and L-MTA + D-MTA in Duke Forest samples were 0.42, 0.11, and 3.49 ng m-3. We also present results from time-resolved experiment of gas and particle products, where 4-hydroxy-3-methyl-but-2-enal, and 4-hydroxy-2-methyl-but-2-enal are proposed as possible precursors to HOM formation.

Keywords: Isoprene, HOMs, methyltreonic acid, methylerythronic acid, methyltartaric acid, secondary organic aerosol.

4AC.3

The Effect of Temperature on Secondary Organic Aerosol Formation from Evaporated Fuels and Aromatic Compounds under Daytime and Nighttime Conditions. JEFF BEAN, Shaokai Gao, Terry Lathem, *Phillips 66*

Secondary organic aerosol (SOA) is an important contributor to ambient concentrations of particulate matter. SOA is formed from oxidation of anthropogenic and biogenic volatile organic compounds (VOCs) in the atmosphere. Chemical transport models (CTMs), such as the Community Multi-scale Air Quality Model (CMAQ) and the Comprehensive Air Quality Model with Extensions (CAMx), provide estimates of SOA formation based on data acquired from environmental chamber experiments and ambient measurements. The model parameters used to calculate SOA must be continuously evaluated and updated to incorporate advances in SOA research. It is important to evaluate model performance for multiple VOC precursors and across a variety of environmental conditions.

The present study compares SOA formation in 7.5 m^3 environmental chambers with box model predictions for evaporative emissions of commercial fuels (gasoline and diesel) and single component aromatics. Experiments were conducted across a range of temperatures as well as under both daytime and nighttime oxidative conditions. Experiments were modeled using the SAPRC box model with the SAPRC07 chemical mechanism and the AERO6 SOA parameters, similar to the SAPRC07TC_AE6_AQ mechanism used by CMAQ version 5.1. Key results from comparisons of modeled and experimental SOA formation at varying temperatures and oxidative conditions will be presented. These results highlight areas where further improvements are needed to increase model accuracy.

4AC.4

Characterization of Isoprene-derived Secondary Organic Aerosols at a Rural Site in North China Plain with Implications for Anthropogenic Pollution Effects.

JIANJUN LI, Gehui Wang, *Institute of Earth Environment, CAS*

Isoprene is the most abundant non-methane volatile organic compound (VOC) and the largest contributor to secondary organic aerosol (SOA) burden on a global scale. In order to examine the influence of high concentrations of anthropogenic pollutants on isoprene-derived SOA (SOAi) formation, summertime PM2.5 filter samples were collected with a three-hour sampling interval at a rural site in the North China Plain (NCP), and determined for SOAi tracers and other chemical species. RO2+NO pathway derived 2-methylglyceric acid presented a relatively higher contribution to the SOAi due to the high-NOx (~20ppb) conditions in the NCP that suppressed the reactive uptake of RO2+HO2 reaction derived isoprene epoxydiols. Compared to particle acidity and water content, sulfate plays a dominant role in the heterogeneous formation process of SOAi. Diurnal variation and correlation of 2-methyltetrols with ozone suggested an important effect of isoprene ozonolysis on SOAi formation. SOAi increased linearly with levoglucosan during June 10-18, which can be attributed to an increasing emission of isoprene caused by the field burning of wheat straw and a favorable aqueous SOA formation during the aging process of the biomass burning plume. Our results suggested that isoprene oxidation is highly influenced by intensive anthropogenic activities in the NCP.

4AC.5

IEPOX Uptake Changes Particle Morphology and Viscosity. NICOLE OLSON, Ziying Lei, Rebecca Craig, Yue Zhang, Yuzhi Chen, Jason Surratt, Andrew Ault, *University of Michigan*

In atmospheric particles, organics become mixed with inorganic species via gas-phase oxidation of volatile organic compounds (VOCs) with subsequent condensation of the low-volatility products, such as isoprene epoxydiols (IEPOX), key products of isoprene photo-oxidation, which leads to the formation of secondary organic aerosol (SOA). Chamber and field studies have observed complex physicochemical properties of SOA, such as liquid-liquid phase separations (LLPS) and viscous or glassy organic phases, that inhibit reactive uptake of gaseous species, lower partitioning of chemical species from particle to gas phase, and lower the relative humidity (RH) at which particles undergo efflorescence and deliquescence. To determine the impact these complex morphologies have on the formation of IEPOX-derived SOA, laboratory experiments were conducted by exposing gaseous IEPOX to acidic ammonium sulfate particles coated with α-pinene and toluene SOA at a range of RH (15-50%).To determine individual particle morphology and viscosity, single-particle microscopic and spectroscopic techniques, including scanning electron microscopy coupled with energy dispersive x-ray spectroscopy (SEM-EDX), Raman microspectroscopy, and atomic force microscopy (AFM), were used. After IEPOX uptake, changes to particle morphology and an increase in particle viscosity were observed, which decreased additional IEPOX uptake and limited subsequent particle growth. Particle phase and viscosity determination is necessary to more accurately predict atmospheric fate of ambient aerosols, and the effect aerosols have on heterogeneous (multi-phase) chemistry, climate, and air quality.

A Simplified Parameterization of Isoprene Epoxydiols Derived Secondary Organic Aerosol (IEPOX-SOA) for Global and Climate Models. DUSEONG JO, Alma Hodzic, Louisa Emmons, Eloise Marais, Zhe Peng, Weiwei Hu, Pedro Campuzano-Jost, Jose-Luis Jimenez, *University of Colorado Boulder*

Isoprene is the most abundant non-methane volatile organic compound in the atmosphere and substantially contributes to secondary organic aerosol (SOA) concentrations globally. Isoprene epoxydiols derived SOA (IEPOX-SOA) is thought to contribute the dominant fraction of total isoprene SOA. IEPOX-SOA depends on aerosol pH and other properties, and cannot be calculated accurately with lumping SOA schemes such as two-product and volatility basis set approaches. Recent modeling studies have found generally good agreement between simulated and observed IEPOX-SOA after including detailed isoprene chemistry. However, these models require high computational cost including the calculations of chemistry, deposition, and transport processes of intermediates (e.g. isoprene peroxy radicals, ISOPOOH, IEPOX, etc.). This makes it difficult to include into climate models for long-term studies. For similar reasons, the latest version of the GEOS-Chem model includes a fixed 3% yield of SOA from isoprene for most model applications, in order to avoid the extra computational cost of the full mechanism. Here we present a simplified parameterization for IEPOX-SOA simulation, based on an approximate analytical solution of the relevant portion of the isoprene chemical mechanism. The IEPOX-SOA yield and formation timescale can be directly calculated using the current model fields of oxidant concentrations, NO, aerosol pH and other key properties, and dry deposition rates. Therefore, the parameterization does not require the simulation of the intermediates with maintaining chemical fidelity for simulating IEPOX-SOA. The simulated IEPOX-SOA with the parameterization shows R^2 of 0.96 in comparison to that with the full chemistry in terms of temporal (timeseries in source region) and spatial (global map) variations. Detailed methodology and evaluation results of the parameterization will be discussed.

4AC.8

Compositional Analysis of Aerosols and Rain Water during Weak South-west Monsoon Period. PRADHI RAJEEV, Prashant Rajput, Gyanesh Kumar Singh, Vikram Choudhary, Amit Kumar Singh, Tarun Gupta, *Indian Institute of Technology Kanpur*

Particulate matter (PM) loading during South-west (SW) monsoon is significantly less over the Indo-Gangetic Plain (IGP) due to frequent wash out by wet precipitation and high convective mixing [Temp: ~ 40 °C; wind speed: ~8 m/s]. However in year 2015, weak SW-monsoon due to El-Niño and positive phase of Pacific Decadal Oscillation (PDO) has resulted in less rainfall (~ 375 mm) than usual (~ 900 mm) over the IGP region. Thus, low wet precipitation has facilitated to assess several characteristic features of aerosols and rain waters during the SW-monsoon. We have conducted a study in the central IGP during SW-monsoon to assess chemical characteristics of ambient atmospheric aerosols ($PM_{2.5}$; n= 42; 42.2 ± 22.4 μg/m3) and individual rain water samples (pH: 6.4−7.6; n = 15). Different chemical constituents like organic carbon (OC), elemental carbon (EC), water-soluble organic carbon (WSOC), water-soluble inorganic species (WSIS), water-soluble total nitrogen (WSTN) and metals have been studied in aerosols. However, in rain water samples, pH, electrical conductivity, WSOC, WSIS and WSTN have been assessed. In aerosol samples, the contribution of secondary inorganic species viz. SO_4^{2-}, NH_4^+ and NO_3^- in WSIS were found to be predominant. In a sharp contrast, HCO_3^- and Ca^{2+} constituted the major fraction of total WSIS in rain waters. Characteristic mass ratios among ionic species in rain waters and aerosol samples suggest that below-cloud scavenging is predominant mechanism of aerosols wash out over the region. The mass contribution of total carbonaceous aerosols (TCA), mineral dust (MD) and WSIS in PM2.5 was found to be 22%, 37% and 35%, respectively. Higher contribution of mineral dust in $PM_{2.5}$ is attributable to significant upliftment of mineral aerosols due to drier weather condition and high wind speed. Mineral dust characteristics in $PM_{2.5}$ have been assessed systematically utilizing elemental ratios of major crustal metals i.e. Fe/Al, Ca/Al and Mg/Al. Our study documents that rain waters over the IGP is alkaline in nature and provides a field-based evidence that fine fraction mineral dust favors the uptake of secondary species like nitrate.

4AC.9

A Multi-Season Investigation of Non-Combustion-Related Emissions of Gas-Phase Organic Compounds in Two Major U.S. Cities. PEEYUSH KHARE, Jenna Ditto, Taekyu Joo, Nga Lee Ng, Drew Gentner, *Yale University*

Emissions from combustion-related sources have historically dominated urban air pollution but non-combustion emissions are now playing an important role in determining the U.S. urban air quality (Khare and Gentner (2017), ACPD). Despite their growing significance, the magnitude, composition, secondary organic aerosol- and ozone- formation potential of non-combustion emissions in the atmosphere are largely understudied. In this study, we present results from our summer and winter air quality measurements in New York City, NY and Atlanta, GA with particular attention to the influence of non-combustion emissions. Gas- and particle-phase samples were collected at the New York State Department of Environmental Conservation (NYSDEC) site located in Queens, NY, a Manhattan facing residential building in Harlem, NYC and, at the Southeastern Aerosol Characterization (SEARCH) site near downtown Atlanta, GA. The collected samples were analyzed using traditional GC-MS, as well as using a very high resolution tandem mass spectrometer (i.e. MS×MS) employing atmospheric pressure chemical ionization and electrospray ionization inline with gas and liquid chromatographic separations, respectively. This provided molecular-level and structural characterization over a broad polarity and volatility range. A diverse suite of emitted organic compounds spanning across a wide polarity and volatility range is studied with special focus on under-characterized halogen- or phosphorus-containing organic pollutants and other intermediate volatility and semi-volatile organic compounds (IVOCs and SVOCs) whose direct and indirect health impacts are well documented. All prominent isomers are identified and reported, and are characterized by their accurate molecular formula, structural elements, and volatility. We report information on the range of urban concentrations of all measured compounds for comparison between the cities and seasons. Concentrations of each compound of interest are tested for least-squares correlation with CO concentrations, a common method for calculating emission since urban emissions of CO are mostly anthropogenic primary emissions, and provide a robust way to compare emissions between cities and scale up emissions with validated CO emissions inventories. Total urban emissions and individual concentrations are summarized by carbon number, compound class, and functionalities across the entire volatility span up to SVOCs. Measured compounds at each site are statistically evaluated for likely co-emissions or covariance via automated full dataset regressions in Igor Pro. We also collected and chemically characterized gasoline and diesel fuel samples from each city and season to constrain the contribution of motor vehicles to observed emissions using source apportionment methods. Our study aims to resolve major knowledge gaps in emissions inventories that are necessary for air quality models and comprehensive air quality policies in an era where non-combustion sources are emerging as key, prevalent factors in urban air quality.

4AC.10

Automated Organic Aerosol Measurement with Quartz Filter-based Thermal Desorption Gas Chromatography Mass Spectrometry (TAG). HAIXIA REN, Mo Xue, Zhaojin An, Wei Zhou, Jingkun Jiang, *Tsinghua University, Beijing, 100084, China*

Rapid characterization and high chemical resolution of organic compounds in atmospheric particulate matter are required in aerosol research, especially when revealing the sources of primary organic aerosol, the formation of secondary organic aerosol and atmospheric evolution of organic aerosol. Real-time characterization is preferable considering the variation and lability of organic aerosol, although it can be very challenging due to the chemical complexity of aerosol, especially characterization at molecular level. In-situ thermal desorption aerosol gas chromatography (TAG) was previously developed to characterize organics in aerosols at molecular level. Briefly, aerosols are collected in a collection cell, then organics in aerosols are thermally vaporized and captured in a cooled trap, finally injected into gas chromatograph (GC) for analysis. However, previously reported either stainless steel impactor or metal-fiber filter based TAG has high risk of residue accumulation, especially under severe particulate matter loading that is frequently encountered in polluted atmospheric environment.

In this study, a quartz filter based TAG, which can be readily disassembled and allows filter replacement, has been developed and evaluated using C7-C40 n-alkanes. The developed device is composed of a quartz filter collection cell, temperature and pressure control system, and combined with commercial gas chromatography mass spectrometry (GCMS) for evaluation. The thermally desorbed organics were trapped by the analytical column. C11-C40 with boiling point from 196 – 525°C was detected with residues of less than 1% and demonstrated repeatability of less than 10% except for C11, C12, and C40. Considering the complexity of organic aerosol, the device was hyphenated with two dimensional gas chromatography (GC´GC-MS) for analysis, and the analytical performance was validated by alkanes, polycyclic aromatic hydrocarbons, sterols, acids, etc. The developed instrument was deployed for hourly in-situ organic compounds analysis of ambient PM2.5 in Beijing, and organic aerosol emissions from residential solid fuel combustion. Results from these field studies will be discussed.

4AC.11

Size and Composition Dependent Seed Particle Growth by α-Pinene Ozonolysis. JUSTIN KRASNOMOWITZ, Michael J. Apsokardu, Chris Stangl, Shanhu Lee, Murray Johnston, *University of Delaware*

Biogenic secondary organic aerosol (BSOA) is a key contributor to particle formation and growth in the atmosphere. In principle, growth mechanisms and rates can be both seed particle size and composition dependent. This work utilizes a flow tube reactor with a 4 minute residence time to study these dependencies. Experiments performed to date were done by exposing monodispersed ammonium sulfate seed particles to varying amounts of highly oxidized molecules (HOMs) produced by α-pinene ozonolysis at low relative humidity (10%) and room temperature. Experiments were performed by first introducing monodispersed ammonium sulfate seeds (40, 60 or 80 nm in diameter) into the flow tube along with a low ozone mixing ratio. Next, α-pinene (14 ppbv) was added to begin HOM production. The ozone mixing ratio was then systematically increased from 30 to 300 ppbv during the course of the experiment to increase the average HOM mixing ratio, which caused an increasing amount of seed particle growth. Particles exiting the flow tube for each increment of ozone mixing ratio were characterized with SMPS (size distribution), NAMS (elemental composition) and ESI-HRMS (molecular composition). To a first approximation, particle growth rates were found to be independent of seed particle size and increased linearly with increasing ozone mixing ratio. The measured growth rates were consistent with a kinetic growth model based on the average HOM mixing ratio in the flow tube for each ozone increment. If anything, the kinetic model slightly underestimated the measured growth rate, suggesting that some multiphase chemistry may have occurred in addition to HOM condensation. Current and planned work will explore the effects of seed particle phase (dry vs. wet ammonium sulfate, organic vs. inorganic seed composition) as well as extend these measurements to smaller seed particle sizes.

4AC.12

Application of Spin Traps to Detect Reactive Intermediates and Reactive Oxygen Species in Secondary Organic Aerosol. STEVEN J. CAMPBELL, Chiara Giorio, Peter J. Gallimore, Svetlana Stevanovic, Branka Miljevic, Steven Bottle, Zoran Ristovski, Markus Kalberer, *University of Cambridge*

The chemical composition and evolution of secondary organic aerosol (SOA) in the atmosphere represents one of the largest uncertainties in our current understanding of air quality. Despite vast research, the toxicological mechanisms relating to adverse human health effects upon exposure to particulate matter are still poorly understood. Studies suggest that particle bound reactive oxygen species (ROS) are a major contributor to observed health effects associated with exposure to ambient particulate matter. ROS is an umbrella term, which encompasses a large range of species including peroxides, oxidised organics, organic radicals and the transition metal-induced formation of peroxides and radicals. Several chemical assays are available for ROS detection, all of which are sensitive to a certain fraction of ROS species in aerosol. However, the role of radicals and reactive intermediates in both the formation and ageing of aerosol, as well as their contribution to the health-relevant properties of ambient aerosol, at present remains highly uncertain. We recently developed a technique to quantify organic radicals in the gas phase by stabilising them with spin traps, and subsequent analysis using various mass spectrometry techniques.[1] Recently, a study by Stevanovic *et al.*[2] introduced the profluorescent spin trap BPEAnit (9,10-*bis*-(phenylethynyl)-anthracene-nitroxide) which has been shown to be capable of quantifying particle-bound radicals in aerosol generated from the combustion of biomaterial and fuel.

In this work, BPEAnit is applied to study the concentrations of particle-bound radicals in SOA. Radical concentrations were estimated for SOA generated from the ozonolysis of α-pinene, β-caryophyllene and limonene in a flow tube, to probe the assays response to SOA formed from biogenic precursors typically found in the atmosphere. SOA is captured in an impinger containing the BPEAnit/DMSO assay, before subsequent analysis using fluorescence spectroscopy. Additionally, the BPEAnit spin trap assay allowed the design of experiments to probe the lifetime of radical species in α-pinene SOA, producing first estimates of organic radical decay in SOA. A pseudo-1st order rate constant of $k = 7.3 \pm 1.7 \times 10^{-3}\ s^{-1}$ was derived, implying a radical lifetime on the order of minutes in fresh α-pinene SOA.

Furthermore, building on our recent work by Giorio *et.al.*,[1] the spin trap PBN (*N*-*tert*-butyl-α-phenylnitrone) was used to trap Criegee intermediates (CIs) present in the aerosol phase, with the resulting adducts analysed using high performance liquid chromatography high-resolution mass spectrometry. Experiments were conducted with this method using SOA generated from β-caryophyllene ozonolysis in a flow tube, demonstrating the technique's unique capability to detect multiple CIs present in SOA. Criegee intermediate concentrations in the aerosol phase were measured to be 4.5 ± 0.7 ng [CI]/µg SOA, providing the first estimate of condensed phase CI concentrations in SOA.

The Effect of Gasoline Car Exhaust on the Photochemistry of α-Pinene. EETU KARI, Liqing Hao, Sini Isokääntä, Arttu Ylisirniö, Ari Leskinen, Pasi Yli-Pirilä, Celia Faiola, Santtu Mikkonen, Annele Virtanen, *University of Eastern Finland*

Biogenic and anthropogenic emission sources emit particles and volatile organic compounds (VOCs) into the atmosphere. Due to the presence of biogenic and anthropogenic emissions in many locations at the same time, potential interactions between the compounds emitted from these two sources has raised particular scientific interest. To clarify the biogenic-anthropogenic interactions, controlled laboratory studies with real emission sources are required. The laboratory studies with real emission sources represent better the complexity of these interactions than the studies with only pure standards, but still allow controlled conditions to investigate the processes in systematic way. In this work, we conducted an environmental chamber study to explore possible anthropogenic-biogenic interactions between a modern gasoline car (VW Golf 1.2 TSI) exhaust and α-pinene under atmospherically relevant conditions.

To investigate the effect of gasoline car exhaust on α-pinene photochemistry, we conducted three kinds of experiments: 1) experiments with only diluted gasoline car exhaust, 2) experiments with α-pinene and diluted gasoline car exhaust, 3) experiments with α-pinene and ammonium sulphate (AS) particles. In experiment type 3) the VOC/NOx ratio was adjusted so that it was comparable to experiment types 1) and 2). Both gas- and particle phases were monitored using Proton-Transfer-Reaction Time-of-Flight Mass Spectrometer (PTR-ToF-MS), Chemical Ionization Atmospheric Pressure interface Time-of-Flight Mass Spectrometer (CI-APi-ToF-MS) with acetate ionization, Aerosol Mass Spectrometer (SP-AMS), and Scanning Mobility Particles Sizer (SMPS).

We found that depending on the experiment in experiment type 1) gasoline car exhaust produced SOA and the formed SOA mass varied due to the changes in exhaust gas composition. From PTR-ToF-MS data, we were able to identify 18 SOA precursors whose reactions with OH-radicals explained 17%-64% from the observed SOA formation depending on the experiment indicating that some important SOA precursors, such as SVOCs, were not detectable by PTR-ToF-MS. In the experiment type 2) we were able to separate 4 factors from particle phase data measured by AMS using positive matrix factorization (PMF) method: HOA factor that was originated from car exhaust, mixed LVOOA factor that was produced by SOA originated from the photochemistry of car exhaust and α-pinene, α-pinene SVOOA factor, and α-pinene LVOOA factor. From PMF results we were able to estimate the formed SOA mass from car exhaust in experiment type 2), when both car exhaust and α-pinene were present in the chamber during the photo-oxidation. After subtracting car exhaust SOA from α-pinene SOA, we were able to conclude that the other compounds than NOx in gasoline car exhaust did not have a significant effect on SOA yield of α-pinene, and that SOA formed from α-pinene photo-oxidation dominated the total SOA mass in each experiment.

The results of this study indicate that in environments, where gasoline car exhaust is mixed with α-pinene, the photochemistry of α-pinene is significantly affected only by NOx. These results demonstrated also the need to study the car exhaust emissions with the instruments that can quantitatively measure SVOCs in order to fully understand the SOA formation from gasoline exhaust.

4AC.14

Formation of Secondary Organic Aerosol from Photo-Oxidation of Benzene. SEBASTIAN H. SCHMITT, Thomas F. Mentel, Jürgen Wildt, Einhard Kleist, Iida Pullinen, Ying Liu, Baolin Wang, Defeng Zhao, Astrid Kiendler-Scharr,
Forschungszentrum Jülich

Understanding the formation of secondary organic aerosol (SOA) is crucial for estimating its impact on the earth's climate as well as on human health and the development of future mitigation and adaptation strategies. The potential of SOA formation from the oxidation of a certain volatile organic compound (VOC) is often expressed as the SOA mass yield being the ratio of formed SOA mass and consumed VOC. Typically, this is determined from single VOC oxidation experiments in atmosphere simulation chambers. Even though the SOA mass yield is an easy to calculate quantity, caution has to be taken to accurately determine it in a specific atmosphere simulation chamber.

Within this study the formation of SOA from the photo-oxidation of benzene was systematically studied in the Jülich Plant Atmosphere Chamber (JPAC) at the campus of Forschungszentrum Jülich GmbH. JPAC is a continuously stirred tank reactor made of borosilicate glass and it was operated with a typical mixing time of 2 minutes and a residence time of 45 minutes. The oxidizing conditions (OH concentrations, NO_x concentrations) were systematically altered in order to study their respective influence on SOA mass formation. A combination of Scanning Mobility Particle Sizer (SMPS), Aerosol Mass Spectrometry (AMS) and Chemical Ionization Mass Spectrometry (NO_3-CIMS) provided novel insights into the formation process of secondary organic aerosol.

The loss of oxidized SOA precursor molecules to the walls of the reaction chamber must be considered for retrieving the most accurate SOA mass yield. For this purpose an already existing correction function was extended, in order to take into account semi-volatile organic compounds with lifetimes longer than the residence time of the chamber. In order to accurately determine this correction function, ammonium sulfate seed aerosol was used to alter the fraction of SOA precursors lost to the chamber wall systematically. Here, the organic fraction of SOA was determined with the AMS while the NO_3-CIMS provided measurements of the oxidized SOA precursors in the gas phase.

After correction of unseeded experiments for wall loss of SOA precursor by the modified correction function, the SOA mass yield of benzene was found to be 28±13 %. A similar yield (29±4 %) was obtained by using seed aerosol with the uncertainty being largely reduced in presence of seed aerosols. Within the accessible range of the steady state measurements, no dependence of the benzene SOA mass yield on OH could be detected. Also, NO_x had no significant influence on the SOA mass yield from benzene photo-oxidation. However the formation of new particles (nucleation) was strongly suppressed by increasing NO_x concentrations.

A comparison of the obtained SOA mass yield results with literature data shows a large variation, likely due to the sensitivity to the operational conditions of the different experiments.

Characterization of Particulate Matter Sources in Summer Using High-Resolution Aerosol Mass Spectrometry in San Antonio. FANGZHOU GUO, Benjamin Schulze, Alexander Bui, Henry Wallace, James Flynn, Matthew H. Erickson, Sergio Alvarez, Alex Kotsakis, Subin Yoon, Sascha Usenko, Rebecca Sheesley, Robert Griffin, *Rice University*

Currently the seventh most populous city in the United States and the second most populous city in Texas, San Antonio has been one of the most rapidly growing large cities in the country over the past decade. As evidenced by an ozone design value in violation of the federal threshold for a recent three-year period (2014-2016), the city suffers from poor air quality. To understand the sources of particulate matter (PM) that contribute to the degradation of San Antonio's air quality, we assembled and deployed a mobile air quality laboratory and operated it in two locations in the southeast (Traveler's World RV Park) and northwest (University of Texas at San Antonio campus) of downtown San Antonio from May 2 through May 30, 2017. Chemical characterization of non-refractory submicron PM (NR-PM1) at high time resolution was conducted using an Aerodyne high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS). Additional measurements included meteorological parameters, trace gas mixing ratios (of ozone, total nitrogen oxides, total reactive nitrogen, carbon monoxide, and volatile organic compounds), and off-line speciation of PM collected using filters. This is the first time that detailed real-time aerosol measurement results have been reported from San Antonio.

From the preliminary results, organic and sulfate aerosols dominated the total aerosol burden, averaging 5.42 mg/m3 (54% of the total mass) and 3.43 mg/m3 (31% of the total mass), respectively. The average concentrations of ammonium (1.21 mg/m3; 11%), nitrate (0.33 mg/m3; 3.6%), and chloride (0.04 mg/m3; 0.4%) were relatively smaller throughout the campaign period. Total aerosol mass concentrations displayed two high-loading periods (May 9-12 and May 27-29), with the first one propelled by both organics and sulfate and the second one dominated by sulfate aerosols.

Positive matrix factorization, in conjunction with meteorological and trace gas data, will be used to apportion the organic portion of NR-PM1 to various types of organic aerosol, including proxies for primary and secondary organic aerosol. Preliminary results indicate atypically large sulfate aerosol plumes; the relative contribution of biogenic and anthropogenic sources to this sulfate will be quantified. In addition, large spikes of biomass burning organic aerosol appear to originate from agricultural fires in Central America. This combination of data will allow us to estimate the fraction of PM in San Antonio in summer that is local and anthropogenic, potentially providing guidance for development of emission control strategies.

4AC.17

Hygroscopic Behaviours of Inorganic/Organic Mixtures Including Ammonium sulfate, Dicarboxylic Acid and Oligomer.

HICHEM BOUZIDI, Andreas Zuend, Jakub Ondrácek, Jaroslav Schwarz, Vladimír Ždímal, *Institute of Chemical Process Fundamentals of the CAS*

Aerosol particles are an important atmospheric constituent, influencing global climate. The hygroscopic growth behaviour of aerosol particles is one of the important parameters controlling these climate effects. Atmospheric aerosol particles are generally complex mixtures of a diversity of inorganic constituents and organic compounds. In many regions, organic aerosol dominates the ambient aerosol mass. It is well established that high-molecular-weight organic compounds like oligomer with molecular masses ranging from 200 to 1600 $gmol^{-1}$ [1], represent an important fraction in atmospheric aerosols, but their interactions with other inorganic/organic, and atmospheric water vapour are not well understood. Moreover, single particle measurements suggest that organic and inorganic constituents are internally mixed in particulate matter [2]. Therefore, Non-ideal interactions between the organic and inorganic aerosol fractions affect water uptake and solubility, may induce Liquid-liquid phase separation (LLPS) into an organic-rich and an aqueous electrolyte phase (phase separation), may affect efflorescence and deliquescence behaviour, and alter the gas/particle partitioning of semi-volatile compounds [3-4]. The presence or absence of LLPS in aqueous mixtures can be computed using a liquid-liquid equilibrium model [3].

Here, the hygroscopic properties of submicron particles under subsaturated relative humidity (RH), composed of ammonium sulfate, dicarboxylic acids including oxalic acid (OA), malonic acid (MA), and oligomer Poly(Ethylene-Glycol) (PEG-300 $(\text{-CH2OCH2-})_n$) with various mixtures and mass ratios are investigated in a laboratory study using a Hygroscopicity Tandem Differential Mobility Analyzer (HTDMA). Those constituents correspond to materials found in the atmosphere in great abundance and, therefore, particles prepared in this study should mimic atmospheric mixed-phase aerosol particles.

The experimental data are compared with predictions from Zdanovskii-Stokes-Robinson (ZSR) mixing rule and Aerosol Inorganic-Organic Mixtures Functional groups Activity Coefficients (AIOMFAC). In addition, particle-phase behaviour, including the prevalence of liquid–liquid phase separation (LLPS), was also modelled with AIOMFAC.

By comparison with HTDMA data, it was also found that the model was capable of capturing the behaviour of different mixtures of AS/PEG/dicarboxylic acids at high RH. Therefore, experimental data could be used for models to improve the estimation of interaction parameter for PEG group (CH2OCH2) with the carboxyl group (COOH).

The work was supported from ERDF "ACTRIS-CZ RI" (No. CZ.02.1.01/0.0/0.0/16_013/0001315).

Accelerated Chemistry in Microdroplets: Reaction of Aldehyde Functionalities in α-Pinene Secondary Organic Aerosol with a Derivatizing Agent. YAO ZHANG, Murray Johnston, *University of Delaware*

Recent studies have shown that reaction rates in microdroplets can be accelerated by several orders of magnitude over similar processes in bulk solutions (Banerjee et al., Analyst 2017, 142, 1399). In the work presented here, α-Pinene Secondary Organic Aerosol (SOA) is analyzed online using droplet assisted ionization (DAI). When the droplets contain both SOA and the Girard T (GT) reagent, fast reaction of aldehyde functionalities in the SOA with the GT reagent give products that are detected with high sensitivity. The reaction proceeds on the order of seconds in droplets, but hardly at all after an hour in bulk solution. The experimental setup to perform accelerated reaction chemistry will be described in detail, along with a discussion of reaction products and potential applications to online molecular characterization of SOA.

Multiphase Product Distributions for Aqueous-phase Oxidation of Water-soluble Organic Compounds in Bulk Solution and Submicron Particles. KEVIN NIHILL, Christopher Lim, James Rowe, Martin Breitenlechner, Alexander Zaytsev, Joshua L. Cox, Frank Keutsch, Jesse Kroll, *MIT*

Atmospheric aqueous-phase oxidation has been identified as a possible source of highly oxidized organic aerosol (OA) observed in the ambient atmosphere. Most laboratory experiments monitoring the oxidation of organic precursors in the aqueous phase have used bulk phase chemistry, but this may not accurately simulate partitioning or concentration conditions of fine particles in the ambient atmosphere. This is suggested by significant differences in the product distributions of experiments that compare oxidation of water-soluble organics in both the bulk and particle phases. This work serves to extend our understanding of atmospheric aqueous oxidation of water-soluble organic compounds by precisely measuring and comparing the aqueous-phase oxidation products of varying carbon-number polyols (water-soluble compounds with formula $C_nH_{2n+2}O_n$) in both the gas and aqueous phases. Through complementary measurements of oxidation products using an aerosol mass spectrometer (AMS) and two proton-transfer reaction time-of-flight mass spectrometers (high sensitivity PTR3s) – one for the gas phase, and one with a gas-phase denuder followed by a thermodesorption unit for aerosol volatilization – we seek to understand the full oxidation product distributions for a variety of polyols. In particular, a more thorough profile of gas-phase products will allow for an improved understanding of how partitioning and concentration effects in aqueous-phase oxidation impacts the chemistry of the atmosphere. Further, we can elucidate the dependence of gas-particle partitioning on the liquid water content (LWC) of the air mass, which may span many orders of magnitude in the atmosphere. This study underscores the need to reproduce atmospheric conditions in the laboratory in order to better characterize the influence of aqueous-phase oxidation on atmospheric organic chemistry.

Exploring the Autoxidation Mechanisms of Aromatic VOCs. RUBY MARTEN, Mao Xiao, Lukas Fischer, Bernhard Mentler, Mario Simon, Martin Heinritzi, Olga Garmash, Christopher R. Hoyle, Andrea Baccarini, Chuan Ping Lee, Houssni Lamkaddam, Imad El Haddad, Josef Dommen, Urs Baltensperger, CLOUD Collaboration, *Paul Scherrer Institute*

It has been shown that both biogenic and anthropogenic aromatic volatile organic compounds (AVOCs) present in the atmosphere are not only important reactants in formation of secondary organic aerosol and ozone, but that they also form highly oxygenated molecules (HOMs) in the gas phase, which in turn will contribute to new particle formation due to their extremely low volatility.[1,2] In urban areas, anthropogenic AVOCs are a major atmospheric component and therefore an important part of the chemistry involved. AVOCs become HOMs after addition of OH^- to the aromatic ring and a subsequent autoxidation route with multiple additions of O2, leading to a high O:C ratio. Although the oxidation mechanism involved has been studied in depth in many laboratory and theoretical experiments, the complete mechanism of autoxidation is still not clear. Furthermore, mass spectrometry data shows clear evidence of 'dimers' of aromatic HOMs formed in the gas phase, another mechanism which remains unexplained.

This work will present results from experiments, focusing on anthropogenic AVOCs, undertaken during the CLOUD 11 (2016) and CLOUD 12 (2017) campaigns at the CLOUD (Cosmics Leaving OUtdoor Droplets) chamber at CERN. Experiments were performed with toluene, naphthalene, and 1,2,4-tri-methylbenzene under varying atmospherically relevant conditions.

A proposed general mechanism of HOM formation for aromatic VOCs will be presented in order to explain the observed products of autoxidation. This mechanism will be based off of state-of-the-art theories[3,4] combined with data collected from the CLOUD campaigns. Reaction rate constants and branching ratios for the different pathways will be proposed, to capture the observed concentrations and time series of HOMs. The general mechanism of aromatic compound oxidation and the associated rates will be presented and the implication of the different pathways in the HOMs production will be discussed.

PIXE Analysis of PM2.5 Atmospheric Aerosols in a Two Year Monitoring in Mexico City. VALTER ARMANDO BARRERA, Raul Venancio Diaz, Javier Miranda, Giulia Calzolai, Silvia Nava, Martina Giannoni, Franco Lucarelli, *CONACYT-CIACYT/UASLP, Mexico*

After more than 25 years of local air pollution monitoring in Mexico City, Particle Matter (PM) is one pollutant that is not decreasing. This is due to many factors, like the well-known geography, the Ozone all year production with the subsequent reactivity in the local atmosphere, and natural or anthropogenic sources; the Metropolitan Area of Mexico City (MAMC), is still growing without control (8 M inhabitants plus 12 M inhabitants in Mexico City basin). Moreover, the number of vehicles (more than 4.5 M) increases with no regulation and finally, there are industrial zones around the megacity.

Last decades, multiple elemental studies have been done for different PM fractions (Miranda et al., 1992, 1998, 2004, 2005; Chow et al., 2002; Barrera et al., 2012; Diaz et al., 2014). However, there is a lot to know of the chemical composition of the PM pollutant in Mexico city in the recent years, mainly the fine fraction or $PM_{2.5}$.

This work presents a Particle Induced X-ray Emission (PIXE) analysis and a source apportionment study of $PM_{2.5}$ in a two-year monitoring campaign, collecting samples in 4 sites to provide a wider knowledge of elemental concentrations. Monitoring sites were located at the southwest and southeast city for year 2009 and for 2010 at southwest and downtown Mexico City. Almost 200 $PM_{2.5}$ samples were collected on a 24 h (from midnight to midnight) sampling base each two days, by using two Teom samplers (medium-volume 1 m^3/h), depositing the particles onto 47 mm diameter Teflon filters, allowing the application of the PIXE technique. Meteorological parameters were obtained from the local network.

PIXE analyses were performed at the 3 MV Tandetron accelerator of the INFN-LABEC laboratory, with a recently installed external beam set-up composed by a Silicon Drift Detector with a large active area (80 mm^2) and 450 mm thickness for low Z element, with proton deflector and an identical SDD detector used just for the detection of medium-high energy X-rays, thus reducing the irradiation time and generating better statistical data (Lucarelli et al., 2014). Each sample was irradiated for ~90 s with a 3.0 MeV proton beam (~2 mm^2 spot, 10 nA to 150 nA intensity). PIXE spectra were fitted using the GUPIX code (Maxwell et al., 1995) and elemental concentrations were obtained by a calibration curve from a set of thin standards of known areal density (Micromatter Inc.). The lighter elements (Na, Mg, Al and Si) concentrations were corrected for self-absorption effects (Calzolai et al., 2010). Also, PIXE technique provide a better analysis for several trace elements that are very useful for aerosol source apportionment (e.g., V, Ni, Cu, Zn, Pb) (Maenhaut, 2015). Uncertainties were determined by a sum of independent uncertainties or an expanded uncertainty method from each analysis (Espinosa et al., 2010).

More than 20 elements were identified by PIXE, representing more than 12% of the $PM_{2.5}$ total mass in the four sites. Maximum concentrations episodes were registered in the two corresponding monitoring zones at Feb 12th, 2009 and June 1st, 2010, mainly due to different industrial zones near the MAMC.

Different multivariate methods were used to determine the number of possible influencing polluting sources for each site, which were then identified through back-trajectory simulations with the HYSPLIT modeling software (Draxler & Rolph, 2010).

Vertical Characterization of Highly Oxygenated Molecules (HOM) Below and Above a Boreal Forest Canopy. QIAOZHI ZHA, Chao Yan, Heikki Junninen, Matthieu Riva, Juho Aalto, Lauriane Quéléver, Simon Schallhart, Lubna Dada, Liine Heikkinen, Otso Peräkyla, Jun Zou, Clemence Rose, Yonghong Wang, Ivan Mammarella, Timo Vesala, Douglas Worsnop, Gabriel Katul, Markku Kulmala, Tuukka Petäjä, Federico Bianchi, Mikael Ehn, *University of Helsinki*

Highly oxygenated molecules (HOM) play important roles in new particle formation (NPF) and secondary organic aerosol (SOA) formation, and therefore have significant effect on air quality, global radiation budget, and climate. In addition to the efforts that have been made in understanding the formation mechanisms of HOMs, increased attention has been drawn to the interaction between HOM chemistry and changing atmospheric conditions.

During the Influence of Biosphere-Atmosphere Interactions on the Reactive Nitrogen budget (IBAIRN) campaign, vertical profile measurements of HOMs below and above the forest canopy were performed using two nitrate ion based Chemical Ionization Atmospheric Pressure interface Time-Of-Flight (CI-APi-TOF) mass spectrometers, for the first time in the boreal forest SMEAR II station during September 2016. The HOM concentrations and composition distributions below and above the canopy were similar in the well-mixed boundary layer condition during daytime. Surprisingly, during night, even though precursor monoterpene concentrations are elevated, much lower HOM concentrations were observed at ground level, as a result of the formation of a shallow decoupled layer attached to the forest floor. The results suggested that near ground HOMs were affected by the changes in the precursors and oxidants, and enhancement of the loss/deposition on surfaces in this layer, while the HOMs above the canopy top were not significantly affected.

One of the main novelties of our study is the detailed measurements of HOM below and above the canopy across a wide range of atmospheric stability conditions. The results highlight the significance of near-ground boundary layer dynamics and micrometeorological processes to the ambient HOMs, and the ground-based HOM measurement are not always representative for the entire boundary layer. This needs to be considered when interpreting measurements that are expected to be influenced by HOM, such as growth rates of new particles.

4AC.23

Fine Particle pH in Urban Guangzhou, a Megacity of South China. ZHISHENG ZHANG, Jun Tao, Leiming Zhang, Zejian Lin, *South China Institute of Environmental Sciences*

Particle acidity is a critical parameter affecting aerosol processes and properties, yet it is poorly constrained in China. In the present study, hourly measurement of particulate and gaseous compositions along with meteorological parameters were observed in an urban site of Guangzhou, a megacity of South China. A total of 4688 sets of data were obtained. These data were used as inputs into ISORROPIA-Ⅱ thermodynamic equilibrium model running in the forward mode to estimate the fine particle pH. Fine particle pH in Guangzhou ranged from 1.3 to 5.7, with a mean of 2.8. It showed a clear diurnal pattern with peak value in the early morning hours and lowest value occurred in the afternoon. Higher fine particle pH were found on polluted cases when the particulate compositions were dominated by nitrate and ammonium. Sensitivity tests were performed by altering inputs to analyze the potential impacts of these variables on particle pH. It showed that NH_3, SO_4, relative humidity (RH) and temperature were the key factors affecting pH in Guangzhou. Under high RH and low temperature conditions, high NH_3 and low sulfate concentrations tended to generate high pH particles.

4AC.24

The Presence of Phenanthrene Oxidation Products in α-Pinene Secondary Organic Aerosol Particles. AMBER KRAMER, Kaitlyn J. Suski, Alla Zelenyuk, Staci L. Simonich, *Oregon State University*

Polycyclic aromatic hydrocarbons (PAHs) are toxic environmental pollutants which are transported globally on fine particulate matter (PM2.5) and monitored in many parts of the world. Phenanthrene is a ubiquitous model three-ringed PAH. Secondary organic aerosols (SOA) are naturally formed through atmospheric reactions of biogenic volatile organic compounds, making up a large fraction of PM2.5, and have been shown to trap and transport PAHs. SOA particles have been shown to consist of highly oxidized organic compounds and reactive oxygen species, which have the potential to react with other organic components such as PAHs, changing the physical properties of the particles and their ability to enhance long range atmospheric transport. The presence of oxidized PAHs has been shown, and needs to be explored to improve atmospheric transport modeling and human risk assessment. In controlled laboratory experiments, ozone reacted α-pinene SOA will be grown with gas phase phenanthrene present. Particles will be monitored for physical characteristics over time, and filters of SOA particles will be collected and analyzed for phenanthrene and phenanthrene oxidation products. Collected SOA filters will be extracted and analyzed using gas-chromatography partnered with mass spectrometry to determine the chemical makeup of the phenanthrene within the particles. The specific compound mixtures will be screened for changes in oxidative potential and developmental toxicity. Preliminary experiments have shown that PHE reacts within SOA system to form mono-hydroxy PHE, and poly-hydroxy PHE compounds. Data also shows that the ratios of compounds continues to change over aging of the particles, and with exposure to ozone.

Clustering of Sulfuric Acid, Bisulfate Ion and Organonitrate C10H15O10N: Thermodynamics and Atmospheric Implications. JASON HERB, Alexey Nadykto, Kirill Nazarenko, Nikolai Korobov, Fangqun Yu, *SUNY at Albany*

Recently, Highly Oxidized Molecules (HOMs) have been suggested to play an important role in New Particle Formation (NPF) in the atmosphere. Although stable clusters containing organonitrates (ONs), a common form of HOM containing nitrogen in addition to carbon, hydrogen and oxygen, and neutral and negatively charged sulfuric acid molecules have been detected in both laboratory experiments under atmospherically relevant conditions and in-situ measurements, the role of ONs in their stability is still poorly understood. In this study, we seek to advance the understanding of the role of ONs in atmospheric NPF by carrying out a Density Functional Theory (DFT) study of the bonding of a selected $C_{10}H_{15}O_{10}N$ organonitrate, N-[2-(1,2-Dicarboxyethoxy)ethyl]-3-hydroxyaspartic acid with H_2SO_4 and bisulfate ion HSO_4^-. The present analysis reveals an important role of the $C_{10}H_{15}O_{10}N$ in the enhanced stability of both ionic and neutral clusters as all the mixed dimers, trimers and tetramers containing $C_{10}H_{15}O_{10}N$ are found to be more stable compared to pure ones. The substitution of the H_2SO_4 molecule with the ON is particularly favorable in the case of negative ions, when the stepwise Gibbs free energy increases by up to ~9 kcal mol^{-1} per step due to the presence of the ON. In particular, the free energies of the formation of $(H_2SO_4)_{n-1}(ON)(HSO_4^-)$ and $(H_2SO_4)n(HSO_4^-)$ via the addition of H_2SO_4 differ by 0.7, 5.45 and 9.2 kcal mol^{-1} at n=2, 3 and 4, respectively, in the favor of $(H2SO4)_{n-1}(ON)(HSO_4^-)$ clusters. The effect of the $C_{10}H_{15}O_{10}N$ on clustering of H_2SO_4 molecules under is smaller, but still considerable as evidenced by ~ 0.7-2 kcal mol^{-1} difference in the formation free energies, also in the favor of ON-containing clusters. This indicates that the $C_{10}H_{15}O_{10}N$ is capable of facilitating the production of fairly large sulfuric acid clusters and may promote in this way atmospheric NPF under favorable conditions.

4AC.26

SOA Formation from Toluene Oxidation in the Presence of Nox: The Importance of Relative Humidity. DAO HUANG, Yunle Chen, Masayuki Takeuchi, Taekyu Joo, Steve Kim, Gamze Eris, Nga Lee Ng, *Zhejiang University*

Toluene is one of the most important anthropogenic volatile organic compounds (VOCs) considering its high concentration in urban and some rural areas and high secondary organic aerosol (SOA) yields. However, in the past decade, knowledge about toluene SOA in the presence of NOx is limited to SOA yield curve under dry conditions and a few scattered yields under humid conditions. Little is known about toluene SOA composition and the effects of relative humidity (RH) on toluene SOA yields and composition. In the present work, a series of toluene photooxidation experiments under dry and humid conditions were performed in the Georgia Tech Environmental Chamber facility (GTEC) to investigate the toluene SOA composition and RH effects. In situ photolysis of HONO was used as an OH radical and NOx sources. Ammonium sulfate was used as aerosol seeds. Particles were chemically characterized using a high-resolution time-of- flight aerosol mass spectrometer (HR-ToF-AMS) and a high-resolution chemical ionization time-of-flight mass spectrometer coupled with a filter inlet for gas and aerosol (FIGAERO-CIMS). Simultaneously, gas-phase compounds were determined by CIMS. Based on experimental results, we obtain different SOA yield curves as a function of organic aerosol (ΔMo) at various RH and compare the particle composition under dry and humid conditions. Generally, the molecular weights of SOA compounds generated under humid conditions is much smaller than that under dry conditions. Under humid conditions, oxygenated organic compounds containing 6 or fewer carbons are the major components of SOA. Under dry conditions, organic nitrates containing 7 or more carbons are the main components of SOA. Further, the evolution of SOA composition over time is also different under dry and humid conditions. We also investigate SOA formation mechanisms under humid conditions by comparing experimental results with MCM modeling. Studying toluene SOA composition and the role of water in SOA formation is important for understanding SOA and haze formation in the real atmosphere.

4AC.27

Modeling the Impact of Cookstove Emissions on Ambient Aerosol in Rural India. BRIGITTE ROONEY, Kirk Smith, John Seinfeld, Ajay Pillarisetti, Rufus Edwards, Lauren Fleming, Sergey Nizkorodov, Tami Bond, Nicholas Lam, Sumit Sharma, Seema Kundu, Shaocai Yu, Pengfei Li, Kelvin Bates, Ran Zhao, *California Institute of Technology*

In India, particulate matter (PM) pollution is a significant cause of health problems and increased mortality. However, specific source contributions to PM have remained largely understudied, as work that has been done has mostly focused on indoor air quality. Within the residential sector, a majority of Indian households still rely on solid biofuels, mainly wood and dung, for cooking. Combustion of solid fuels is known to produce more aerosol than liquid fuels, and thus cookstove use has been identified as a potential significant source of PM pollution.

To better understand the production of ambient aerosol by the residential sector in rural India, we have undertaken a series of modeling experiments using the Community Multiscale Air Quality (CMAQ) atmospheric chemistry transport model. This work incorporates updated emissions inventories and time varying boundary conditions, and represents some of the highest resolution (1km and 4km grid cells) modeling of its kind. By varying such parameters as fuel type and emission factors, we are able to determine the fraction of PM attributable to cookstove use. Our expectation is that the results will further incentivize the transition from household use of solid fuels to more modern liquid fuels in order to reduce the health risks associated with aerosol pollution.

4AC.28

A Laboratory and Modeling Investigation on the Effects of Ammonia Uptake on SOA Composition and Its Potential Impacts on Air Quality.

JULIA MONTOYA-AGUILERA, Mallory Hinks, Jeremy Horne, Shupeng Zhu, Donald Dabdub, Sergey Nizkorodov, *University of California, Irvine*

Particulate matter (PM) consists of suspended particles in the atmosphere large enough to diminish visibility, affect global temperatures by absorbing or scattering light, and contribute to cloud formation by acting as cloud condensation nuclei (CCN). The importance of inorganic nitrogen contribution to PM is well recognized and included in air quality models. Less understood is the contribution of nitrogen-containing organic compounds (NOC) to secondary organic aerosols (SOA), a major component of PM. Currently, the reactive uptake of ammonia (NH_3) leading to the formation of NOC in SOA remains unaccounted for in air quality models. Ammonia is ubiquitous in the atmosphere and is emitted largely from agricultural processes. Intensifying use of NH_3-based fertilizers suggest NH_3 levels will continue to rise in the future. It is important to better characterize this NH_3 uptake process, not only because of its potential effects on SOA composition, but also because, if the uptake is efficient, NH_3 may be unavailable to contribute to inorganic PM formation.

This study investigates the effects of NH_3 on SOA formation, optical properties, and chemical composition. Anthropogenic (toluene, n-hexadecane) and biogenic (isoprene, limonene) volatile organic compounds (VOCs) are oxidized in a smog chamber at various relative humidity and NO_x levels. After SOA formation, a pulse of gas-phase NH_3 is introduced into the chamber. Particle growth is monitored with a scanning mobility particle sizer (SMPS). A proton-transfer-reaction time-of-flight mass spectrometer (PTR-ToF-MS) is used to track VOCs. An NH_3 analyzer is used to measure the decay of ammonia onto particles (and chamber walls) and a time-of-flight aerosol mass spectrometer (ToF-AMS) is employed to monitor the increase in N:C ratios in the organic components as well as increases in ammonium ion in the aerosol particles. Subsequently, samples are collected and analyzed via direct analysis in real time mass spectrometry (DART-MS). These techniques are used to determine to what extent NH_3 reacts with SOA to form NOC (as opposed to being neutralized to ammonium ions by organic and inorganic acid vapors). Additionally, wavelength dependent mass absorption coefficients of SOA extracts are measured. Results indicate that the rate and maximal extent of the NH_3+SOA→NOC reactions vary depending on the SOA system. Of the SOA studied, limonene SOA was the most reactive when exposed to NH_3. DART mass spectra revealed that exposure of limonene SOA to NH_3 converted up to 20% of SOA compounds to NOC. The experimental results were incorporated into the University of California, Irvine - California Institute of Technology (UCI-CIT) model, a state-of-the-art airshed model used to evaluate air quality in the South Coast Air Basin of California (SoCAB). A surface reaction of NH_3 with SOA was implemented into the model to estimate the impact on NH_3 and $PM_{2.5}$ concentrations in the SoCAB region. Results indicate the chemical uptake of NH_3 by SOA can potentially deplete gaseous NH_3 concentrations, leading to indirect reductions in the amount of ammonium nitrate and ammonium sulfate in PM. Moreover, the impact of this chemical uptake was investigated on a larger scale by incorporating the results into the Community Multiscale Air Quality Modeling System (CMAQ) model, with a domain covering the continental United States. The CMAQ model simulations show that inclusion of the NH_3+SOA→NOC chemistry decreases the concentration of inorganic components of $PM_{2.5}$ but increases biogenic SOA, especially in the southeastern United States.

4AC.29

Secondary Organic Aerosol Production from Healthy and Aphid-Stressed Scots Pine Biogenic Volatile Organic Compound Emissions in Different Oxidant Systems. FATEMEH KHALAJ, Celia Faiola, Angela Buchholz, Eetu Kari, Arttu Ylisirniö, Minna Kivimäenpää, Jarmo Holopainen, Annele Virtanen, *University of California, Irvine*

Vegetation emits copious amount of hydrocarbon compounds into the atmosphere, called biogenic volatile organic compounds (BVOCs). BVOCs amount to about 90% of global total VOC emissions. Most BVOCs, based on their high reactivity, have short life times (a few hours), and readily react with atmospheric oxidants to produce lower volatility oxidation products. Thus, BVOCs are major precursors of atmospheric secondary organic aerosols (SOA). Biotic stressors, such as increased insect herbivory, enhance BVOC emissions and modify the types of BVOCs emitted. For example, methyl salicylate (MeSA) is a plant hormone induced by aphid herbivory. However, it is unclear how plant stress emissions such as MeSA alter SOA production. In this study, healthy and aphid-stressed Scot Pine BVOC emissions were used to evaluate SOA production during oxidation via ozonolysis or photooxidation. SOA was generated in Kuopio, Finland a 10 m3 batch reaction chamber composed of FEP material. For comparison to the healthy and stressed Scots pine experiments, SOA was generated from single component standards, α-pinene (OH and O3), and MeSA (OH only). For the plant SOA experiments, Scots pine saplings were enclosed in a dynamic enclosure with flow rates ~4 lpm, their emissions were trapped onto adsorbent cartridges overnight, and then thermally desorbed into the batch reaction chamber targeting ~20 ppb initial monoterpene mixing ratios at the start of the experiment. The initial suite of BVOCs that acted as SOA precursors during the Scots pine experiments was characterized via thermo-desorption gas chromatography mass spectrometry (TD-GC-MS). BVOC concentrations were monitored continuously throughout oxidation with a high resolution proton transfer reaction mass spectrometer (PTR-ToF-MS; Ionicon, Inc.). Particle size distributions and composition were monitored with a scanning mobility particle sizer (SMPS; TSI, Inc.) and high resolution time of flight aerosol mass spectrometer (HR-ToF-AMS), respectively. Results of BVOC concentrations demonstrated that aphid herbivory led to higher mixing ratios of sesquiterpenes in the reaction chamber. The average sesquiterpene mixing ratio was 1.84±1.12 ppb and 8.74±0.04 ppb for healthy and stressed Scots pine experiments, respectively. For comparison, the average monoterpene mixing ratio was 21.68±4.44 ppb and 22.60±1.36 ppb for healthy and stressed Scots pine experiments, respectively. The average MeSA mixing ratio was 1.23±1.05 ppb and 0.97±0.02 ppb for healthy and stressed Scots pine experiments, respectively. The detailed molecular speciation of initial BVOC composition will be presented. Additionally, an overview of SOA mass yields and composition will be shown to compare between healthy and stressed Scots pine SOA and the two single component standards for the two oxidant systems studied.

Characteristics of PM2.5 and Gaseous Precursor in Urban and Background Areas in Korea. TAEHYUN PARK, Jihee Ban, Seokwon Kang, Gyutae Park, Kyunghoon Kim, Min Seok Song, Seung Hwan Lee, Jannatul Maoa, Hye Jung Shin, Jong Sung Park, Seung Myung Park, Jun Oh, Mindo Lee, Sang-Bo Lee, Jeong Soo Kim, Dong-Gil Yu, Taehyoung Lee, *Hankuk University of Foreign Studies, Yongin, South Korea*

The Korean peninsula is a great place to study different sources of the aerosols: urban, rural and marine. In addition, Seoul is one of the large metropolitan areas in the world and has a variety of sources because half of the Korean population lives in Seoul, which comprises only 12% of the country's area. Also, Baengnyeong island located in the west of Korean peninsula is an important place where we can observe the behavior of air pollutants emitted from Northeast Asia and measure the background concentrations of air quality in Korea. To understand the chemical composition of aerosol from long-range transport and local sources better, both particulate matter and gaseous precursors need to observation. In this study, we plan to measure the chemical compositions of $PM_{2.5}$ (Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}, SO_4^{2-}, NO_3^-, Cl^-, WSOC) and gaseous precursors (HNO_3, NH_3, SO_2) by AIM(Aerosol Ion Monitor, URG Corporation), PILS(Particle Into Liquid Sampler) coupled with TOC (Total Organic Carbon, SIEVERS 850) and gas monitors (SO_2 (43C, Thermo Scientific), NH_3 (EAA 911-0016, Los Gatos Research)) in the Seoul and Baengnyeong island Intensive Air Quality Monitoring Stations during the two time of intensive period (Jan. 15 – Feb. 10, 2018 and March, 2018). The AIM and PILS-TOC is providing the ionic chemical compositions of $PM_{2.5}$ and the concentrations of gaseous precursors and water soluble organic carbon with 1-hour time resolution. The scientific goal of this study is to characterize chemical properties of $PM_{2.5}$ and gaseous precursors to understand the role of the long-range transport from northeast Asia and influence of the local sources. The presentation will provide an overview of the ionic compounds of $PM_{2.5}$ and gaseous precursors in the air pollution plume at Seoul (urban site) and Baengnyeong island (background site).

Reactions between SO_2 and Organic Peroxides and Their Role as Atmospheric Sinks of Sulfur. SHUNYAO WANG, Shouming Zhou, Ye Tao, Jianhuai Ye, Jian Zhen Yu, Jennifer G. Murphy, Jonathan Abbatt, Arthur W. H. Chan, *University of Toronto*

While SO_2 oxidation has long been recognized as a source of particulate sulfate and acid rain, the underlying mechanisms by which SO_2 reacts with multiple organic species remain poorly understood. Previous chamber studies have shown that organic peroxides from monoterpene ozonolysis can react with SO_2, suggesting that organic peroxides (ROOR or ROOH) could be an important sink of SO_2. In this work, we investigate the kinetics and mechanisms of reactions between SO_2 and organic peroxides. Upon SO_2 exposure in a bulk solution, the depletion of both ROOR and ROOH standards (including cumene hydroperoxide, tert-butyl hydroperoxide, 2-butanone peroxide, benzoyl peroxide and tert-butyl peroxide) was monitored using iodometric-spectrophotometric method and was found to be significant. The reaction rate constant will be derived from the decay of total S (IV) concentration (monitored by ion chromatography) and speciated organic peroxide concentration (monitored by atmospheric pressure chemical ionization tandem mass spectrometry). In addition to the formation of inorganic sulfate, organosulfates (OS) were also formed, and were quantified by electrospray ionization ion mobility mass spectrometry (ESI-IMS) under negative mode with collision induced dissociation, using both synthetic biogenic OS and commercial OS as calibration standards. In addition to bulk solution studies, we also conduct flow tube experiments to study the reactive uptake coefficients (γeff) for SO_2 and biogenic SOA (i.e. α-pinene, isoprene). Measured kinetic parameters can be further applied to the atmospheric models to assess the potential impacts. Our work will improve understanding of how the interaction between SO_2 and organic peroxides will influence the formation of biogenic SOA under atmospheric-relevant conditions.

The Effect of Chemistry and Particle Total Surface Area on Loss Rate of Highly Oxidized Multifunctional Organic Molecules (HOMs).

IIDA PULLINEN, Jürgen Wildt, Einhard Kleist, Monika Springer, Cheng Wu, Stefanie Andres, Sebastian H. Schmitt, Andreas Wahner, Thomas F. Mentel, *University of Eastern Finland*

The loss of Highly Oxidized Multifunctional Organic Molecule (HOM) peroxy radicals on existing particle surface as reported here might have implications on atmospheric chemistry. Particle densities used in the experiments correspond to mass loadings observed in the Troposphere. HOM-RO_2 lifetimes in the atmosphere are also likely to be longer than in our experiments, leading to proportionally higher importance of condensational loss onto particles.

HOMs are a group of organic molecules produced by oxidation of VOC, and are generally considered to have low to extremely low vapour pressures, which makes them potentially important in particle formation and growth processes in the atmosphere. Better understanding the formation and loss processes of these molecules can thus lead to a better understanding of particle formation.

HOM formation can be explained by peroxy radical chemistry: a HOM peroxy radical (HOM-RO_2) is formed via autoxidation, followed by a termination via classical peroxy radical pathways. The main stable end product pathways are those leading to formation of ketones or alcohols (RO_2+RO_2’), and hydroperoxides (RO_2+HO_2).

When studying the formation and loss processes of HOMs in chamber experiments we discovered that there were indications that the particles were participating photochemistry, in that they acted as a condensation sink to both HO_2 and HOM-RO_2. This was observed during determinations of effective uptake coefficients of HOM on particles. For HOM with extremely low vapour pressures uptake coefficients are 1, i.e. uptake by particles is collision limited. At high particle surface ($> 1.0 \cdot 10^{-3}$ m^2m^{-3}), uptake coefficients for some HOM seemed to be higher than 1, while for other HOM loss rates decreased with increasing particle surface. Our hypothesis is that also peroxy radicals are lost on particles. When in presence of high particle surface, losses of peroxy radicals on particles affect the production rates of termination products. Lower production rates mimic too high uptake coefficients and vice versa higher production rates can mimic decreases of uptake coefficients at higher particle surface.

Examples for this behaviour are the HOM dimers. Lower peroxy radical concentrations due to efficient losses on particles decrease production rates and pretend uptake coefficients higher than collision limited. Another observation indirectly indicates very efficient HO_2 losses on organic particles. HOMs preliminary identified as hydroperoxides show the same behaviour as dimers and other HOM preliminary identified as ketones show the opposite trend. We suggest that the HO_2 losses lead to lower production rates of hydroperoxides with the result of unrealistically high uptake coefficients. The apparent lowering of uptake coefficients for ketones suggests that the HO_2 losses can also lead to an increasing production rate in RO_2+RO_2 reactions.

4AC.33

Secondary Organic Aerosol Formation from Methylfurans by Nitrate Radical Oxidation. TAEKYU JOO, Masayuki Takeuchi, Matthew Alvarado, Nga Lee Ng, *Georgia Institute of Technology*

An important activity that contributes to both primary organic aerosol (POA) and secondary organic aerosol (SOA) formation is biomass burning. Recent studies about biomass burning SOA formation demonstrate that a large fraction of SOA is produced from an unidentified pathway. These studies suggest an important contribution of nontraditional precursors to SOA formation from biomass burning, such as furan derivatives. Methylfurans are one of the main furan derivatives that are emitted by biomass burning. However, our current understanding of SOA formation from methylfurans is extremely limited, and even less attention has been paid to nighttime oxidation of this class of compounds from biomass burning activities. Here, we investigate SOA formation from 2- and 3-methylfuran by nitrate radical (NO_3) oxidation at the Georgia Tech Environmental Chamber (GTEC) facility. NO_3 is formed from NO_2 + O_3 reaction, and NO_3 subsequently reacts with NO_2 to make N_2O_5. The VOC:N_2O_5 ratio was set around 1:4 to ensure peroxy radicals react with NO_3. Oxidation products were measured in real-time with High Resolution Time-of-Flight Chemical Ionization Mass Spectrometer (HR-ToF-CIMS) coupled with a Filter Inlet for Gases and AEROsols (FIGAERO). This setup allows the measurement of both gas- and particle-phase composition during the oxidation process. A High Resolution-Time of Flight-Aerosol Mass Spectrometer (HR-ToF-AMS) was deployed to measure the bulk elemental composition of SOA. The VOC decay was measured with Gas Chromatography Flame Ionization Detector (GC-FID) and the increase of aerosol mass concentration was measured with a Scanning Mobility Particle Sizer (SMPS). Aerosol mass continued to increase after all 2- and 3-methylfuran were consumed, indicating a large contribution of higher-generation oxidation products to SOA. Organic nitrate ($RONO_2$) contribution was around 10-15% to the total organics measured by HR-ToF-AMS. Multiple monomer and dimer species that contain an -ONO_2 functional group were also detected by FIGAERO-ToF-CIMS. These results indicate that the $RONO_2$ species are also important in terms of SOA formation, which have not yet been considered in 2- and 3-methylfuran SOA studies to date.

4AC.34

Soil Spreading of Organic Waste Products: Source of Secondary Oorganic Aerosols. RALUCA CIURARU, Corentin Berger, Pauline Buysse, Yvain Carpentier, Céline Decuq, Cristian Focsa, Sophie Genermont, Sylvie Gosselin, Sabine Houot, Julien Kammer, Florence Lafouge, Benjamin Loubet, Nicolas Visez, Denis Petitprez, *INRA*

The agricultural soils emit volatile organic compounds (VOCs) that contribute to the formation of secondary pollutants such as ozone or secondary organic aerosols (SOA).

Soil VOC emissions are lower than the VOCs released from the canopy. Nevertheless, it has been showed that under certain conditions (i.e., temperature, soil water content…) and for specific ecosystems, VOC emissions from soil could reach the same order of magnitude as canopy emissions (Peñuelas et al., 2014). Data on VOC released from agricultural soils are relatively scarce although they are recognized as large contributors of methanol and acetone to the atmosphere (Bachy et al., 2018).

Organic waste products (OWPs) are used in agriculture as organic amendments to improve soil fertility. The valorization of different types of OWPs from farms (bovine manure, pig slurry…), urban origin (sewage sludge, green waste) or industrial origin (sweets, etc.) is currently promoted as a substitute for mineral fertilizers. OWPs have a wide variety of characteristics due to their origin and the treatments that they may undergo before spreading and this diversity of characteristics could have a significant impact on gaseous and particulate emissions following soil application. There are few studies quantifying the concentrations and emission rates of gaseous compounds emitted from organic waste products, and those studies primarily address their odorant properties in order to identify suitable odor abatement techniques (Feilberg et al., 2015). Some of these laboratory studies have quantified the VOCs emissions from OWPs, including non-methane hydrocarbons VOCs, sulfur compounds, nitrogen compounds and oxygenated volatile organic compounds (Feilberg et al., 2015). Chemical transformations of these atmospheric organic compounds can further lead to products of lower volatility that subsequently partition into the condensed phase.

The aim of this study is to investigate VOC emissions, their subsequent reaction with ozone and SOA formation from agricultural soil amended with different OWPs. The experiments are currently performed in an atmospheric chamber coupled to an aerosol flow tube. A high panel of scientific equipment allows the physical and chemical characterization of the VOCs and freshly formed aerosols (proton transfer mass spectrometer, scanning mobility particle sizer…). Aerosol sampling on filters allows their chemical and molecular characterization by off-line analysis (gas chromatography, time of flight secondary ions mass spectrometry, laser desorption/ionization time of flight mass spectrometry).

PRAPPE: Trace Element Interaction with Organic Compounds in Urban and Crustal PM. JOSEPH SALAZAR, David Pfotenhauer, Frank Leresche, Fernando Rosario-Ortiz, Michael Hannigan, Brian Majestic, *University of Denver*

As part of a larger study, we present field data from the Platte River Air Pollution and Photochemistry Experiment (PRAPPE), aimed at understanding the interactions between organic carbon and trace elements in atmospheric particulate matter (PM). One transformation pathway of organics in the atmosphere is radical oxidation. One possibly unexplored route of radical formation is iron in aqueous suspension via the Photo-Fenton reaction. In Fenton Chemistry, UV light reacts with iron (III) to produce iron (II) and hydroxyl radicals. In turn, the hydroxyl radicals oxidize organic compounds. In this portion of the study, we investigate the role of metals in this process by collecting simultaneous PM2.5 samples in three regions: urban, rural, and a mixture between the two. Sampling was accomplished during the summer (Aug. 2017) and winter (Dec. 2016 - Mar. 2017), where 24-hr PM2.5 samples were collected at three different sites on the Eastern Colorado plains. At each site, three filters were collected: two Teflons (mass, ions, soluble metals, and total metals) and 1 quartz filter (EC/OC and organic speciation). Part of the Teflon filter was also analyzed by x-ray absorption near edge structure (XANES) spectroscopy to probe the oxidation state of iron in the PM. Understanding the oxidation state of the iron is an important factor in determining its solubility, where Fe(II) tends to be the more soluble of the iron species, and thus would be most important in radical production. In addition, XRF maps of each sample were collected to understand intraparticle composition. During the winter, the urban and mix site showed the same levels of iron concentration (average = 2.70 ng/m^3) while the crustal site showed significantly less iron (average = 0.78 ng/m^3). This is one of two abstracts for this project. Here, we work to quantify and understand the state of iron in the different sources of PM while another abstract will present data on the influence of iron on the formation of hydroxyl radical upon photoirradiation of aqueous PM extracts and on the effect of irradiation on the light absorbance properties and hydroxyl radical formation potential of the extracts. These results will be the first attempt in the understanding how iron processes organic compounds through reactive oxygen species in PM collected from urban and rural sources.

4AC.36

Analysis of Gas-phase and Particulate Reaction Products from High-NOx Photooxidation of n-dodecane: Influence of Temperature and Relative Humidity on Secondary Organic Aerosol Formation. HOUSSNI LAMKADDAM, Aline Gratien, Edouard Pangui, Mathieu Cazaunau, Marc David, Jean-Michel Polienor, Murielle Jerome, Cécile Gaimoz, Bénédicte Picquet-Varrault, Jean-François Doussin, *LISA, Universités Paris-Est-Créteil et Paris Diderot*

Organic aerosol (OA) plays an important role on atmospheric chemistry, climate change and public health. While OA particles can be directly emitted into the atmosphere, they can also be introduced in the atmosphere by secondary organic aerosol (SOA) formation. However our current knowledge of oxidation pathways and chemical composition of the SOA is limited and poorly understood considering the difficulty of the chemical transport model (CTM) to predict the OA mass in the atmosphere (Heald et al., 2011). It results to large uncertainties in the estimation of the impact on climate and air quality of the atmospheric aerosols.

In this context, the aim of this work is to study SOA formation from oxidation of precursors such as long chain alkanes which represent a substantial fraction of the unresolved complex mixture in diesel fuel (Gentner et al, 2012). Beside the fact that it represents a relevant class of compound for the urban atmosphere, long chain alkanes are also very interesting model-molecule to investigate the sensitivity to different reaction pathways of the organic matter, i.e. fragmentation, functionalization or oligomerization, during its atmospheric oxidation.

The experiments were carried out in the CESAM chamber (http://cesam.cnrs.fr) (Wang et al., 2011). It is a 4,2 m3 stainless steel chamber which allows to conduct experiments at different temperature and relative humidity, constant pressure and under a very realistic actinic flux. It is also equipped with a large range of analytical instruments to characterize the gas-phase and particulate reaction products.

In particular, the present work assesses the effect of temperature (from 10 to 30°C) and relative humidity (from <1 to 70%) on the high-NOx photooxidation of n-dodecane. Aside aerosol mass production, the mechanism was also investigated by measuring SOA composition. Mechanistic pathways of the gaseous and particulate products will be proposed.

This work was supported by the European Community within the 7th Framework Program, section “Support for Research Infrastructure – Integrated Infrastructure Initiative”: EUROCHAMP-2 and also by the French National Programme of Atmospheric Chemistry (PN-LEFE CHAT). CNRS-INSU is acknowledged for supporting the CESAM chamber as national instrument.

4AC.38

Reactions between Small Atmospheric Carbonyls and Ammonium Sulfate. MELISSA GALLOWAY, Daisy Grace, Melissa Sebold, Rachael Holappa, Jessica Ackendorf, *Lafayette College*

The chemical composition of atmospheric aerosol is complex and poorly understood. Aqueous reactions of aldehydes with amines or ammonium salts have been implicated in atmospheric brown carbon formation processes. Recent work has started to identify the products of these reactions, especially those responsible for visible light absorbance. However, few studies have looked at the reaction products of ammonium with a mixture of aldehydes. Supercritical fluid chromatography-electrospray ionization-mass spectrometry equipped with a photodiode array is tested as a viable technique for separation and identification of the reaction products of mixtures of small, water soluble carbonyls (e.g. glyoxal, methylglyoxal, and glycolaldehyde) with ammonium sulfate. We present information on the efficacy of this separation technique as well as structural and mass comparisons between products formed from the reaction of a single aldehyde with ammonium and a mixture of aldehydes and ammonium sulfate. The results of these studies will allow us to better understand the aqueous chemistry occurring in atmospheric aerosol droplets.

4AC.39

Molecular Insights from Ultrahigh Resolution Orbitrap Mass Spectrometry on Aqueous Phase Processing of Ambient Biomass Burning Emissions Influenced Po Valley Fog and Aerosol. MATTHEW BREGE, Tyler Leverton, Stefania Gilardoni, Stefano Decesari, Marco Paglione, M. Cristina Facchini, Lynn Mazzoleni, *Michigan Technological University*

Ambient samples of fog water and PM_1 aerosol were collected in the Po Valley (Italy) over four consecutive days in the winter of 2015. The Po Valley has an established history of regional biomass burning emissions influence and aqueous aging processes resulting in significant concentrations of brown carbon. Four samples of fog water and eight samples of extracted PM_1 aerosol filters (day and night samples) were analyzed by ultrahigh resolution Orbitrap mass spectrometry using both electrospray ionization and atmospheric pressure photoionization methods. The water-soluble organic matter of the samples was fractionated prior to analysis using a 2-step solid phase extraction procedure for HULIS. This fractionation method facilitated the observation of additional less easily ionized condensed aromatic species. Thousands of distinct molecular formulas were assigned to the monoisotopic masses of each sample, and were categorized into elemental groups and sub-classes based on the observed number of oxygen, nitrogen and/or sulfur atoms in the formulas. An atypically large frequency of molecular formulas containing nitrogen and sulfur were observed. Many of which could be attributed to multifunctional organonitrates and organosulfates, however aromatic species with lower numbers of oxygen abundant in atmospheric pressure photoionization could not. In general, higher numbers of CHNO species were observed in aerosol samples and higher numbers of CHOS species were found in fog water. The observed molecular trends were related to the atmospheric conditions to determine their likely origins. The overlapping collection time periods between the two sample types, and the progressive chronological sampling, allowed for a unique perspective on chemical transformations within this humid atmosphere.

4AC.41

Effect of Aqueous-Phase Processing on Formation and Evaluation of the Organic Aerosol during Fog Processing in Kanpur, India. ANIL KUMAR MANDARIYA, Tarun Gupta, S.N. Tripathi, *Indian Institute of Technology Kanpur*

Kanpur is a polluted urban location in India, situated at the center of Indo-Gangetic Plain which witnesses several fog episodes every year during winter time and these fog episodes are linked to the enhanced in the production of secondary organic aerosol (SOA) via aqueous-phase processing. This study highlights the aqueous-phase processing of organic aerosol (OA) and relative importance of OA factors during the processing periods of fog in heavily polluted site affected by biomass emissions in the winter time. Our results show that loading of OA and inorganic species (NO_3^-, SO_4^{2-}, NH_4^+, and Cl^-) changes drastically from period of Pre-Fog-Haze to Fog and Fog to Post-Fog-Haze as compare to period of Pre-Fog to Pre-Fog-Haze and Post-Fog-Haze to Post-Fog during fog processing while mass fractions remain approximately steady, indicating the wet removal through fog droplets. Vankrevelen slopes vary throughout the periods of fog processing indicating different aging mechanism during different stages of fog processing. In contrast of aqueous phase processing mass of more oxidized oxygenated organic aerosol (MO-OOA) slightly varies throughout the fog processing periods which indicate that aqueous-phase processing plays a minor role in the formation of it as it shows poor correlation (R=0.23) with aerosol liquid water content (ALWC). In addition, fog processing has dominant impact on the formation of Low oxidized OOA (LO-OOA), oxidized biomass burning OA (O-BBOA) and biomass burning OA (BBOA) and their contribution to OA varies substantially as a function of fog periods as indicated by good significant ($p<0.05$) correlation (R=0.66, 0.66 & 0.59 respectively) with ALWC and typical fragments ions i.e. $C_2H_2O_2^+$, $C_2O_2^+$, $CH_2O_2^+$ (typical fragment ions of methylglyoxal and glyoxal) and CH_3SO^+, $CH_2SO_2^+$, $CH_3SO_2^+$ (fragment ions of methanesulfonic acid (MSA)). These results also highlighting the wet scavenging of LO-OOA, O-BBOA, and BBOA more efficiently through fog droplets as these OA components decrease significantly during the period of fog through the fog processing as compare to MO-OOA. In addition, oxygen to carbon ratio (O/C) of OA and secondary organic aerosol (SOA) also varies during the periods of fog with the maximum during Pre-Fog and Post-Fog periods as compare to rest of periods while O/C is higher during a period of Fog as compare to Pre-Fog-Haze and Post-Fog-Haze.

4AC.42

Gas-Particle Partitioning of the Traffic-Emitted Semi-Volatile Organic Compounds Measured in Fort McHenry Road Tunnel.

CHIRANJIVI BHATTARAI, Andrey Khlystov, *Desert Research Institute*

The volatility of ambient organic aerosol compounds is essential to understanding their contribution to ambient particulate matter (PM) concentrations, their atmospheric lifetime, and their effect on human health. Only recently it has been realized that primary organic aerosols (POA), such as those emitted by vehicular traffic, contain a large fraction of semivolatile substances. Data on volatility of individual semi-volatile compounds emitted by traffic is still scarce. We have sampled gas and particles phase semi-volatile organic compounds (SVOC) using Teflon-impregnated glass fiber filters (TIGF) and XAD-4 resin at Fort McHenry Tunnel (Baltimore, MD, USA) in February and August 2015 to estimate the saturation vapor pressure of about 100 individual semi-volatile organic compounds. The tunnel passes under the Baltimore Harbor and carries traffic for Interstate 95, the main highway on the East Coast of the U.S. The daily traffic volume during this study was approximately 55,000 vehicles per day. Concentrations of individual compounds were determined by extracting TIGF and XAD-4 samples separately and analyzing the extracts using electron impact (EI) GC/MS for polycyclic aromatic hydrocarbons (PAHs), oxy-PAHs, alkanes and cycloalkanes in the range of C12 to C40, and hopanes/steranes. Using gas-particle partitioning theory, we estimated the saturation vapor pressure of individual SVOCs. In general, the estimated values for C12 to C40 n-alkanes agreed well with the available data. We will also present comparison of estimated vapor pressures for other compounds for which literature data is available.

4AC.43

Secondary Organic Aerosol and Organochloride Formation from Alkanes. DONGYU S. WANG, Lea Hildebrandt Ruiz, *University of Texas at Austin*

Alkanes account for nearly 40% of anthropogenic volatile organic compounds emitted each year. Enhanced alkane mixing ratios have been reported within unconventional natural gas production regions. The air quality impacts of anthropogenic alkanes remain highly uncertain due to scarce ambient and laboratory data on the precursor abundance and oxidation product composition, especially for larger alkanes.

Environmental chamber experiments were carried out to investigate the photo-oxidation of linear, branched, and cyclic C_{8-12} alkanes. Nitrogen oxides (NO_x) were added to simulate polluted environments. Chlorine radical was added to simulate early morning oxidation chemistry and effects of atmospheric aging. A High-Resolution Time-of-Flight Chemical Ionization Mass Spectrometer (CIMS) was used to characterize the gas-phase chemical composition. A Filtered Inlet for Gas and AEROsol (FIGAERO) was coupled to the CIMS to collect aerosol and to analyze its molecular composition via thermal desorption. The thermal desorption signal of individual species, when viewed as a function of the desorption temperature, can be used to assess the relative volatility of particulate compounds. As an extension of this 1-D thermogram representation, a 2-D thermogram framework was developed to visualize the particle-phase chemical composition and volatility distribution simultaneously using unit-mass-resolution FIGAERO-CIMS data. A clear correlation between molecular mass and volatility of organic aerosol components was observed using the 2-D thermogram. An Aerosol Chemical Speciation Monitor (ACSM) was used to quantify the SOA mass. The observed SOA yields were much higher than SOA yields previously reported for OH-initiated oxidation of alkanes under high NO_x conditions. A comparison of OH-alkane and chlorine-alkane 2-D thermograms shows that oligomers and highly oxidized organic compounds contributed to the high SOA yield observed for chlorine-initiated oxidation of alkanes. Both FIGAERO-CIMS and ACSM measurements show trace amounts of alkane-derived organochloride reaction products, and a potential formation pathway is proposed. The chamber relative humidity was varied between 0 to 80% to explore its effect on SOA formation. Alkane-derived organochloride formation was suppressed under humid conditions, consistent with the proposed reaction mechanism. Overall, the results suggest that long-chain anthropogenic alkanes could have greater contribution to aerosol loading over its atmospheric lifetime than previously thought.

4AC.44

Gas and Particle Phase Products of the Reaction of 1-Decanol with OH Radicals in the Presence of NOx. ALLISON DAVIS, Xiaoxi Liu, Jose-Luis Jimenez, Paul Ziemann, *University of Colorado-Boulder*

The products and mechanism of secondary organic aerosol (SOA) formation from the OH radical-initiated reaction of 1-decanol in the presence of NOx were investigated in an environmental chamber. Controlled environmental chamber studies provide data concerning gas-phase chemistry as well as gas-particle partitioning and particle-phase reactions, which are necessary for developing detailed chemical models for use in predicting atmospheric fate of volatile organic compounds (VOCs) and SOA formation. Understanding the fate of alcohols in the atmosphere is of increasing importance in rural and urban environments. Alcohols are widely used in industrial solvents and as fuel sources and are emitted into the atmosphere by vegetation. In this study, particle-phase products were analyzed in real time with a thermal desorption particle beam mass spectrometer and off-line following collection onto filters. Subsequent analysis of functional groups by derivatization-spectrophotometric methods developed in our lab allowed quantification of carbonyl, hydroxyl, carboxyl, ester, nitrate, and peroxide functional groups. Derivatized products were also separated by high performance liquid chromatography for molecular quantitation by UV absorbance and identification using chemical ionization-ion mass spectrometry. Identified products consist of highly multi-functional compounds containing various combinations of functional groups and include hydroxydinitrates and dihydroxynitrates, and some also contain an aldehyde group which may promote the formation of low volatility oligomers and cyclic hemiacetals. A suite of experiments employing these methods probed the role of functional groups in aging SOA. Identification and quantification of first, second, and older generation products is necessary for understanding the influence of particle composition on gas-particle partitioning, particle-phase reactions, and SOA properties such as viscosity. Measurements of gas and particle phase products of alcohol oxidation also offer insight into the chemical mechanism and physical processes leading to SOA formation.

4AC.45

Secondary Organic Aerosol Formation of OH and NO3 Initiated Reactions of 1,3-Benzenediol. ZACHARY FINEWAX, Joost de Gouw, Paul Ziemann, *University of Colorado*

Biomass burning is the second largest emission source of volatile organic compounds (VOCs) and largest of particulate matter (PM) globally. Previous studies measuring emissions from biomass burning have identified 1,3-benzenediol (resorcinol), a semi-volatile organic compound (SVOC) emitted as a pyrolysis product of lignin, a biopolymer found in wood. To date, there have been no studies on the gas-phase oxidation of this compound, which may be an important precursor for secondary organic aerosol (SOA) from biomass burning.

To study the reactions of resorcinol that could occur in a biomass burning plume, OH and NO_3 radical-initiated reactions (simulating daytime and nighttime, respectively) of resorcinol in the presence of NO_x were conducted in an 8 m^3 FEP Teflon environmental chamber operated in batch mode. OH radical-initiated reactions were performed by photolysis of methyl nitrite (CH_3ONO) in the presence of NO by blacklights, and NO_3 radical-initiated reactions were performed by thermal decomposition of N_2O_5. Because of the low volatility of resorcinol and thus potential for loss to the chamber walls, studies of the gas-phase chemistry were conducted by adding resorcinol while photolysis of CH_3ONO or thermal decomposition of N_2O_5 was already occurring in the chamber. This allowed for reaction to occur prior to wall loss because of the high reactivity of resorcinol with both oxidants. SOA produced by these reactions was measured with a thermal desorption particle beam mass spectrometer (TDPBMS) and scanning mobility particle sizer (SMPS), and was collected on Teflon filters to quantify the SOA yield. The gas-phase compounds were measured and quantified by Proton-Transfer-Reaction Mass Spectrometry (PTR-MS) and collection onto denuders to quantify VOCs, and SVOCs that exist in both the particle and gas-phase. Molecular identification and quantification was conducted by high-performance liquid chromatography (HPLC) and chemical ionization ion trap mass spectrometry (CI-ITMS) on SOA filter and denuder extracts through the use of commercially available and authentic standards collected from HPLC fractions.

SOA and molecular yield calculations assumed complete reaction of the added resorcinol, which is appropriate given the calculated kinetics of resorcinol reactions with OH and NO_3 radicals, and the expected much longer timescale for vapor wall loss in the environmental chamber. The product distribution of the SOA from OH-initiated reactions is dominated by 1,2,3-benzenetriol and 1,2,4-benzenetriol, with minor contributions from benzenetetraols, 5-nitro-1,2,3-benzenetriol, and nitroresorcinol isomers. In the OH radical reaction, hydroxybenzoquinone and dihydroxybenzoquinone are generated as gas-phase products both by gas-phase reaction and multiphase chemistry involving oxidation of benzenetriols and benzenetetraols by nitric acid. This was determined through additions of ammonia, and monitoring the reduced loss of benzenetriols from the particle phase. The SOA mass yield of 0.61 for the OH radical-initiated reaction was over a factor of 2 higher than the yield of 0.27 from the NO_3 radical-initiated reactions, while the products were 4-nitroresorcinol, 2-nitroresorcinol, and hydroxybenzoquinone. The presence of nitroresorcinol in both the gas-phase and particle-phase indicate that these compounds are semivolatile. The results of this study highlight the importance of resorcinol oxidation to SOA formation during the day compared to at night.

Clustering Process of Glyoxylic Acid Involving Gas-phase Hydration Reaction: Implications for the Atmospheric Models. Ling Liu, Oona Kupiainen-Määttä, XIUHUI ZHANG, *Beijing Institute of Technoloy*

Atmospheric aerosol nucleation mechanism is important but still not clear, especially different reactivities of precursors can induce various chemical reactions during the clustering process besides the cluster formation through hydrogen bond. However, chemical reactions are not fully considered in most of the nucleation processes. Herein, the clustering process of glyoxylic acid (GA), the most abundant oxocarboxylic acids in the atmosphere, involving gas-phase hydration reaction are studied by Density Functional Theory combined with Atmospheric Clusters Dynamic Code. The hydration reaction of GA can occur in clustering process with the conversion ratio up to 85%, and the product can further participate in the clustering process. GA with its hydration reaction can enhance cluster formation rate. The differences in cluster structure and property induced by hydration reaction lead to the discrepancies in cluster formation rates and pathways. These results shed some light on the discrepancy between atmospheric models and field measurements and have important implications for atmospheric model improvement.

Reactive Oxygen Species (ROS) Activity Map Induced by PM2.5 in 10 Different Cities, China. SHEXIA MA, Yanshan Lv, Xiaoying Li, Yangyang Zhang, Xuejun Liu, Mei Zheng, *South China Institute of Environmental Sciences, MEP*

Numerous epidemiological studies have confirmed that exposure to ambient fine particulate matter (PM2.5) may increase cardiopulmonary mortality and morbidity. Oxidative potential (the ability of ambient particles to generate ROS) is a more relevant measurement when attempting to link aerosols and health end points. In this study, we quantify the oxidative potential of ambient particles collected during four seasons in 10 cities, China, using the dithiothreitol (DTT) assay, and aim to investigate the spatial and seasonal heterogeneity of ROS induced by PM2.5 in China. We find that PM2.5 are generally more reactive in clean days (<75µg/m3) than in polluted days (>75µg/m3), the increased health risk is gradually reduced per unit PM2.5 mass when PM2.5 concentration was above 75µg/m3. Annual average of blank-corrected DTT loss ranged from 1.42 to 25.50 pmol DTT min-1µg-1 PM among the 10 sites with a mean of 6.122±7.086 pmol DTT min-1µg-1 PM. The highest DTT activity was observed at the Guangzhou and the lowest occurred at the Baoding, with the ratio of average DTT loss is 5.25. The spatial distribution of DTT activity generated by PM2.5 collected in 10 different cities shows that higher DTT loss in coastal sites such as Guangzhou, Dalian, Fuzhou etc., lower DTT loss in inland sites, such as Baoding, Dezhou, Handan etc, which is the first spatial ROS activity map in China. There is a clear seasonal variation with highest activity in summer and lowest activity in spring, the average ratio of 1.97, indicated different sources and chemical properties of PM2.5 had significant effect on ROS generation. Slightly higher relative risks (RRs) of ambient PM2.5 were observed in Guangzhou and Dalian with lower PM2.5 level, while the lowest RRs were observed in Beijing with higher PM2.5, which was consistent with ROS activity map in the present study, suggesting that smaller particles, which might contain more toxins from anthropogenic emissions, can more easily reach the acinar part and promote oxidative stress and inflammation.

4AE.2

Indoor-Outdoor Particulate Relationship and Its Metal Bound Concentrations in Domestic Homes of 'World Heritage Site' Agra, India. HIMANSHI ROHRA, Ajay Taneja, *DR. B.R.A. University, Agra, India*

The present work endeavours to parade the influence of particle size and associated metals (Al, Ba, Ca, Cu, Fe, K, Mg, Mn, b, Cd, Co, Zn) within coarse (2.5-10µm), accumulation (2.5-0.25µm) and ultrafine (UF) (<0.25µm) particulate matter (PM) ranges in living rooms of residential homes with their subsequent comparison with outdoor levels at Agra, India. Higher PM concentrations were measured through cascade impactor in indoors (PM10= 264 µg/m3; PM2.5= 195 µg/m3) as compared to outdoors (PM10= 212 µg/m3; PM2.5= 153 µg/m3); both surpassing the WHO benchmark targets. In view of size segregated aerosol, q-UF particles dominated indoor (37%) and outdoor (28%) concentration levels; accounting as major health concern. Poor relationship between indoor-outdoor particle sized levels and coarse and fine PM indicate heterogeneity of sources in concurrent with wash out of particles during precipitation events in sampling tenure. A unimodal lognormal distribution of PM was obtained with preference to droplet mode peak (1.0-0.5µm) in outdoors that shifted to smaller size (0.5-0.25µm) in indoors. For K, Co, Zn, modal shifting in indoor vs outdoor aerosol distribution were observed. The applied regression model further inspected the infiltration capacity of varied particle size modes in different housing conditions. Shifting of particles towards q-UF range in indoors of roadside homes impacted resident exposure to toxic particles. This work prerequisites in designing pollution control strategies to achieve a healthier indoor living environment in this area.

4AE.3

Effect of Particle Morphology on Performance of an Electrostatic Air–Liquid Interface Cell Exposure System. TA-CHIH HSIAO, Jing-Chi Lin, Hsiao-Chi Chuang, Tsun-Jen Cheng, *National Central University*

The particle morphology can affect the performance of electrostatic-precipitator air–liquid interface (ESP-ALI) cell exposure system as well as cell toxicity. In this study, three types of monodisperse aerosols—spherical sucrose particles, nonspherical soot aggregates, and silver aggregates/agglomerates—were selected to evaluate the collection efficiency at a flow rate ranging from 0.3 to 1.5 lpm. To quantify the particle morphology, the fractal dimension (Df) of testing aerosols were characterized. At identical conditions, the penetration rate for fine particles (dp = 100–250 nm) under different operating conditions was correlated with a characteristic exponential curve using a dimensionless drift velocity (Vc/Vavg,r) as the scaling parameter. For ultrafine particles (UFPs, dp< 100 nm) with different particle morphologies, the particle penetrations in the ESP-ALI were similar, but their diffusion losses were not negligible. By contrast, for fine particles, the collection efficiency of soot nanoaggregates (Df = 2.29) was higher than that of spherical sucrose particles. This might be due to the simultaneous influences of the electric field–induced alignment and the flow field–induced alignment. Furthermore, based on Zhibin and Guoquan's Deutsch model, a quadratic equation was applied to fit the experimental data and to predict the performance of the ESP-ALI.

4AE.4

Determination of Inhalation Exposure due to the Use of Eyebrow Powders. HYEON-JU OH, Taewon T. Han, Gediminas Mainelis, *Rutgers, The State University of New Jersey*

Consumers may be exposed to inhalable aerosols when they apply cosmetic products; however little is known about the extent of such exposures. Here we investigated inhalation exposures when applying five types of eyebrow powders using two types of brushes and determined the mass-based inhaled and deposited aerosol dose. For this project, the powers were applied to mannequin's eyebrows in a realistic manner. The "inhaled" aerosol was sampled through two stainless-steel tubes installed in the mannequin's nostrils for real-time measurement by a Grimm optical particles counter (model 1.108, Grimm Technologies Inc., Douglasville, GA) and collected on filters for gravimetric analysis. The aspiration rate through the nostrils of the mannequin was 10.8 L/min. Experiments with each product were repeated three times. The Grimm measured the inhaled particulate matter (PM) mass concentration for Total Suspended Particles (TSP), PM10, and PM4, and particle size distribution; a cyclone (GK 2.69, Mesa Labs, Inc.) was used to collect PM10, and PM4 inhaled powder fractions. The original powders and the fractions of airborne powders (PM10 and PM4) were characterized using a scanning electron microscope (SEM) (FESEM, Zeiss Sigma). The concentrations measured by the Grimm were 120.5 – 334.4 µg/m3 (TSP), 56.04 – 206.4 µg/m3 (PM10), and 22.2 – 46.8 µg/m3 (PM4), while the concentrations measured by gravimetric analysis were 134.6 – 277.3 µg/m3 (TSP), 43.7 – 136.9 µg/m3, (PM10) and 21.2 – 53.7 µg/m3 (PM4). When deposition by mass was calculated using ICRP deposition model, most of the inhaled powder mass deposited in the head airways (almost 79%), while less than 6% of deposition occurred in the alveolar region. The SEM analysis showed the presence of nanoparticles and their agglomerates in the original and airborne state of all powder products. The results show that determination of potential exposure to respirable particles stemming from cosmetic powder application is feasible through a realistic simulation. In addition, the data show that the concentrations of particulate matter fractions inhaled during eye powder applications could be quite substantial. Future studies will consider potential health effect due to such short-term exposures.

4AE.5

Personal Exposure Monitoring Using Integrated Sensors and Cloud Computing. SEPEHR MAKHSOUS, Angela Chavez, Igor Novosselov, Alexander Mamishev, *University of Washington*

Direct measurements of time and size-resolved particle concentrations are of major importance personal exposure assessments, air quality studies, and pollution monitoring. Human exposure to particulate matter (PM) is associated with multiple adverse health effects including cardiovascular disease, cardiopulmonary disease, and lung cancer. A variety of methods is currently used to measure particle concentrations, including traditional gravimetric filters, aerodynamic particle sizers, beta attenuation monitors and scanning electrical mobility sizers. These methods are highly accurate, but their large size and high price make them impractical for use as personal monitors or area monitor that can be used for detailed mapping of the occupational exposure. Applications demand more practical instruments that are compact, automatic, and low-cost without forgoing sizing accuracy and reliability. Additionally, information about real-time spatial and temporal distribution PM concentrations is essential to prevent exposure and create more effective intervention strategies. Integrated Sensors and Cloud Computing (ISCC) platform provides personal PM exposure assessment. We present the development and evaluation of a low-cost PM ISCC system which uses compact, low-cost Optical Particle Counter (OPC) integrated with an ATMEL microcontroller, a Bluetooth module, and a Wi-Fi chip installed on a Printed Circuit Board (PCB.) The monitor is connected to a smartphone mobile application that allows the user to access data in real time or store it for future examinations. Results of the test show that the system is capable of identifying and classifying PM in real time. Multiple monitors can be connected to a secured cloud for real-time mapping of the facility allowing to take preemptive actions and avoid hazardous health episodes.

4AE.6

Exposure to Polycyclic Aromatic Hydrocarbons (PAHs) in PM10 at Urban Area of a Semi-Arid Region of India. AMIT MASIH, *St. Andrew's College, Gorakhpur, India*

Polycyclic Aromatic Hydrocarbons (PAHs) are toxic air pollutants (TAPs) that have the potential to cause serious and adverse health effects and damage to the environment. These pollutants differ from other primary air pollutants such as sulphur dioxide, nitrogen dioxide, total suspended particulates (TSP) and respiratory suspended particulate matter (RSPM) in the respect that even at substantially lower concentrations; their health effects are carcinogenic in nature. Particulate matter from an urban residential site within Agra city (a semi-arid region) were collected using respirable dust samplers for a span of one year (2010-2011) in order to study the concentration and exposure profiles of PAHs. The samples were extracted with dichloromethane using an automated Soxhlet Extraction. The extracts were analyzed for 17 target Polycyclic Aromatic Hydrocarbons (PAHs). The total PAH (TPAH) concentrations were 27.96 ± 2.3, 22.24 ± 2.1, and 34.38 ± 3.0 ng m-3, respectively, during summer, monsoon and winter seasons. The combined mean concentration of TPAH was 28.19 ngm-3 for all seasons. Benzo(b)fluoranthene, Benzo(g,h,i)perylene, Benzo(b)fluoranthene and Indeno(1,2,3-cd)pyrene were the chief PAHs found in the samples collected from this urban region. The average TPAH percentage based on the number of rings were 1% (2-ring), 2% (3-ring), 24% (4-ring), 48% (5- ring), and 25% (6-ring). Dibenz(a,h)anthracene contributed the highest carcinogenic exposure equivalent (4.09 ng m-3) followed by Benzo(a)pyrene (2.80 ng m-3), Benzo(b)fluoranthene (0.453 ng m-3) and Benzo(k)fluoranthene (0.338 ng m-3), accounting for approximately 50%, 35%, 6% and 4% of the total carcinogenicity of particulate PAH in this urban region, respectively.

Keywords: Particulate Matter, PAH, Carcinogenic Potencies, Semi Arid Region

4AE.7

Data Requirements for Mapping Long-Term Air Pollution with Mobile Short-Term Measurements. RIVKAH GARDNER-FROLICK, Joshua Apte, Kyle Messier, *University of Texas at Austin*

New large-scale approaches to air quality data collection have the potential to substantially advance understanding of human exposure to outdoor air pollution, which varies sharply in space and time. For example, some methods use mobile monitors or temporarily stationed sensors to provide highly spatially resolved data. One inherent limitation is that these methods provide sparse temporal resolution for any given location, raising the question of their ability to monitor long-term trends. Here, we investigate whether a series of short-term measurements can adequately represent long-term average concentrations at a monitoring site. To do so, we conduct a Monte Carlo subsampling analysis of 2011-2017 Bay Area Air Quality Management District (BAAQMD) 1-hour measurements of black carbon (BC), nitric oxide (NO), nitrogen dioxide (NO_2), fine particulate matter ($PM_{2.5}$), carbon monoxide (CO), sulfur dioxide (SO_2), and ultrafine particulate matter (UFP) at multiple locations in the San Francisco Bay Area, California and 2012-2014 Southeastern Aerosol Research and Characterization (SEARCH) Network 1-minute measurements of BC, NO, NO_2, and CO in Atlanta, Georgia. Methods developed using the BAAQMD and SEARCH data ultimately will be applied to air pollution data collected in the San Francisco Bay Area using Google Street View cars. In this dataset, 1-Hz measurements of air pollution are matched to the nearest 30-meter road point and analyses can be performed for each location or for larger road segments.

We use random and structured subsampling to estimate the number of observations needed to achieve an accurate (within ±10%) estimation of the annual mean. The geometric standard deviation of continuous measurements, for both 1-minute and 1-hour time intervals, is descriptive of air quality at a site and is highly predictive of the number of samples required to estimate the mean for a specific pollutant at that site. Across all locations, pollutants tend to cluster together, having a similar geometric standard deviation and required number of samples. The pollutant with the lowest number of required samples is CO, which requires 32 independent observations. The pollutant with the highest required number is NO, with 428 samples. While pollutants tend to cluster together across all monitored locations, a few points have significantly different required sample numbers. For example, the average required sample number for BC is 112, while the required sample number at the Forest Knolls site is 490. These breaks in clustering can be attributed to extremely variable seasonal and diurnal patterns, with the breaks occurring at a given location in a predictable manner. These overall trends hold for both random and structured sampling schemes, corresponding to different real-world field study designs. Given the highly correlated nature of air quality measurements, we found that independent measurements are more important than the length of the measurement period. The results hold important implications for future air quality study design and the practicality of using disparate monitoring methods to collect the most useful information. A small number of discrete measurements, such as those gathered from mobile monitoring, can be highly predictive of annual averages.

4AE.8

Impacts of E-Cigarettes Consumptions on the Air Quality of Vape Shop and Its Nearby Areas. LIQIAO (VICKY) LI, Charlene Nguyen, Yan Lin, Yifang Zhu, *University of California, Los Angeles*

With the rapid growth of e-cigarette (e-cig) market in the U.S, there is an increasing number of independent retail specialty shops (vape shops) that exclusively sell e-cig. The consumption of e-cig in the vape shop might bring a new emission source for aerosol exposure in its indoor environment and nearby businesses. In this study, we selected a representative vape shop in Los Angeles and recorded the number of vaping puffs in every 10 minutes in the shop for four days. Meanwhile, we measured real-time $PM_{2.5}$ concentration and particle number concentration (PNC) in the vape shop as well as its nearby business (~ 3 m away) and outdoor area (~6 m away). Weekly average nicotine concentrations were also measured in each site. The average concentration (SD) of $PM_{2.5}$, PNC and nicotine in the vape shop was 426 (1283) microgram/m^3, 1.89 (2.14)*10^4 /cm^3, and 1.71 microgram/m^3, respectively, which were much higher than those in nearby business (i.e. $PM_{2.5}$: 16.3 (9.3) microgram/m^3; PNC: 8.42 (19.7)*10^3 /cm^3; nicotine: 1.29 microgram/m^3) and outdoor areas (i.e. $PM_{2.5}$: 17.2 (14.0) microgram/m^3; PNC: 8.96 (5.04)*10^3 /cm^3). The number of vaping puffs were significantly correlated with $PM_{2.5}$ concentration ($r=0.74$, $p<0.001$) and PNC ($r=0.71$, $p<0.001$) in the vape shop, indicating the significant contribution of e-cig consumption to indoor aerosols. On the day with the highest average puff number, $PM_{2.5}$ and PNC in the vape shop were significantly correlated with those in nearby business and outdoor area ($p<0.05$), suggesting the impacts of vape shop on nearby air quality. Thus, the secondhand emissions of aerosols in the vape shop potentially impacted on both its and nearby indoor environment.

4AE.9

Personal Exposure to Particulate Matter While Commuting. VÂNIA MARTINS, Susana Marta Almeida, Tiago Faria, Carolina Correia, Inês Cunha-Lopes, Nuno Canha, Evangelia Diapouli, Manos Manousakas, Konstantinos Eleftheriadis, *C2TN, IST, Universidade de Lisboa, Portugal*

Numerous epidemiological studies have demonstrated associations between traffic-related air pollution exposure and a variety of negative human health outcomes. As more commuters are spending a considerable amount of their daily routine inside vehicles it is increasingly relevant to study exposure levels to harmful pollutants. Depending on pollutant, mode of travel and travel distance, the exposure while commuting during along trafficked corridors may constitute a substantial fraction of the total daily exposure. Information regarding the air quality variations when commuting through a city can help the citizens to make more informed decisions on possible avoided emissions when choosing a transport mode and reduce their exposure to air pollutants.

This study aims to assess urban air quality experienced during commutes on different transportation modes. Continuous measuring portable monitors were used during journeys through the city of Lisbon by bus and car. The study continuously tracked not only particles mass and number and black carbon during each journey, but also included collection of PM2.5 and PM10 samples using Personal Environmental Monitors. The chemical characterisation of the PM collected on the filters was carried out in order to assess the commuters’ exposure to PM components.

The values found inside the vehicles when commuting were higher than those measured at urban background monitoring stations, a fact which underlines the need to assess personal exposure by acquiring data directly in the microenvironments where people spend their time.

This work is funded by LIFE Index-Air Project (LIFE15 ENV/PT/000674). C2TN/IST authors gratefully acknowledge the FCT support through the UID/Multi/04349/2013 project.

4AE.13

Uptake of Tobacco Related Reduced Nitrogen Species to Aqueous Aerosols. PETER DECARLO, Anita Avery, Erin Katz, Michael Waring, *Drexel University*

Indoor and outdoor summertime measurements of aerosol composition identified a unique organic signature in the indoor dataset. Measurements of organic aerosol composition in an unoccupied classroom showed a high fraction of the organic mass was attributed to reduced nitrogen species identified by ions in the mass spectra of the general formula: $C_xH_yN_z$. Positive Matrix Factorization of the organic aerosol showed 25-29% of the indoor aerosol was attributable to this indoor source. Through subsequent controlled laboratory experiments, these reduced nitrogen related ions were identified as originating from aged residual tobacco smoke volatilizing from surfaces or clothing in the indoor environment. Controlled laboratory experiments using deposited tobacco smoke in a pyrex vessel in coordination with observational data provided evidence of reactive uptake through acid base chemistry. Further experiments with deposited e-cigarette emissions showed similar behavior initially, but with increasing residence time, e-cigarette residue resulted in stable chemical signatures of nicotine and other e-cigarette liquid constituents (glycol and flavorings) compared to the chemical transformation observed for cigarette residue. While the results are generated from indoor observation of these species, the acid-base reactive uptake mechanism of reduced nitrogen species is applicable to outdoor aerosols and expected to be important in areas where amines and other reduced nitrogen compounds are prevalent.

4AE.14

Community-Level Spatial Mapping of Ultrafine Particle Number Concentration. PRADEEP S. PRATHIBHA, Ray Yeager, Aruni Bhatnagar, Jason S. Su, Jay R. Turner, *Washington University in St. Louis*

The Green Heart Project is a prospective study examining linkages between urban vegetation and cardiovascular health. This association could be mediated by several factors, including the effect of vegetation on local air quality. The study is being conducted in Louisville, KY, where a 1900-acre region has been chosen for long-term monitoring of major urban air pollutants. A 575-acre contiguous region within the domain serves as the intervention area where mature vegetation selected based on ecological compatibility and pollutant abatement characteristics will be installed for near-road as well as widespread neighborhood-scale ‘greening’. The remainder of the study domain serves as the non-intervention (control) area. As part of this study, we are estimating residential level exposure to ambient air pollution with measurements being conducted in the intervention and control areas both before (baseline) and after planting.

To date, pilot studies have been conducted in the control and intervention areas using a mobile platform with ultrafine particle (UFP) number concentration measured at one-second time resolution. An interstate highway with ~4 m high noise barrier bisects the study domain, and rush hour UFP concentrations <10 m downwind of the barrier were up to 45 times greater than background levels. Consistent with previous studies, UFP concentrations returned to background levels within a short distance (<150 m) of the highway. Measurements are also conducted along major arterial roadways and residential streets, and repeated under varying traffic and dispersion conditions. In spring 2018, baseline measurements will expand to include black carbon (BC) and CO_2 on the mobile platform and NO_x ($NO + NO_2$) through a time-integrated passive sampler network; additional parameters will be added as the study progresses. A vegetation planting strategy informed by the baseline measurements will be implemented in fall 2018; post-intervention air quality measurements will be conducted thereafter.

4AE.15

Exposure of Children to Particulate Matter and Chemical Elements in Urban Environment. Tiago Faria, Marina Almeida-Silva, VÂNIA MARTINS, Inês Cunha-Lopes, Carolina Correia, Catarina Galinha, Célia Alves, Susana Marta Almeida, *C2TN, IST, Universidade de Lisboa, Portugal*

Introduction

Particulate matter (PM) is a concern due to the adverse health effects it causes on human health. These effects are linked to the chemical components particles contain and their size and the efficiency of pulmonary deposition. Children spend more than 80% of their time indoors. Therefore, it is necessary to develop the best strategies to reduce PM exposure in various microenvironments in order to reduce health effects. The objective of this study was to quantify the daily exposure of children to PM and their chemical compounds considering different size fractions.

Methodology

Ten children aged 5 to 9 living and studying in the city of Lisbon were selected to be part of this study using personal particle samplers for 3 days.

The particles were collected on Teflon filters using a personal cascade impactor (PCIS) connected to a Leland Legacy SKC pump which sampled particles in the size ranges <0.25, 0.25-0.5, 0.5-1, 1-2.5 and > 2.5 µm. The mass concentrations of the particles were determined gravimetrically. All samples were chemically analyzed by ICP-MS in order to determine the concentration of major and trace elements present in PM. In addition to this sampler, the children carried a monitor to make real-time measurements of PM2.5 concentrations, a particle number counter to measure the number concentration of particles between 10nm and 1µm, and a microaethalometer to measure black carbon concentrations. These equipments were accompanied by a GPS that registered the coordinates of the routes of the children. At the same time, the children fill a logbook every 15 minutes, indicating the main activities carried out indoors and outdoors, as well as the activities carried out by others that can affect the exposure, such as food confection or smoking.

Results

The results of activity logs and GPS were combined with the mass and numerical concentrations of PM and black carbon in order to identify the microenvironments that contributed most to children's exposure. The analysis of the filters allowed to evaluate the size distribution of the particles and to calculate the children's exposure to different chemical elements. The inhaled dose was calculated considering the measured concentrations, the time activity patterns of each child and the inhalation rate. The results showed the importance of the indoor environment, especially of the house and the classroom, for children's exposure to particles.

Conclusions

This study allowed understanding the children exposure to PM in the various microenvironments where they remain and the respective inhaled dose. The study of the particle size distribution and their chemical constituents was an essential input for dosimetry models that aim to evaluate the particles that reach the different regions of the body and thus estimate potential health effects.

Characterization of Nanoparticle Containing Formulations before and after Spraying on Textile Surfaces: The Influence of Surface Active Substances on Aerosol Formation Relevant for Inhalation. FRANK BIERKANDT, Sandra Wagener, Jutta Tentschert, Harald Jungnickel, Peter Laux, Andreas Luch, Lars Hillemann, Paul Bergelt, *Federal Institute for Risk Assessment (BfR)*

The growing application of engineered nanomaterials (ENM) and especially the use as constituents in numerous spray products (e.g., cosmetics, coating or cleaning products) increase the possibility of human exposure via inhalation. A detailed investigation of their behavior and toxic potential is therefore necessary. Adverse effects associated with aerosol inhalation are connected to the size and shape of ENM (e.g., rod-like particles) - amongst others - as these factors influence accessibility within the lungs. Moreover, the composition of the sprayed formulation and the resulting aerosol can also impact the toxicity as compounds adsorbed on any ENM may alter its properties as e.g. cellular uptake or reactivity. Also, certain formulations may carry substances into areas which are normally inaccessible (i.e., Trojan Horse effect). Thus, characterization of spray formulations and their influence on the fate of ENMs in solution as well as after aerosolization is essential and shall be addressed in this work. In addition to this, the alteration of the ENMs upon uptake in cellular systems will be investigated, combined with toxicity testing.

The emulated spray formulations - based on pure water and ethanol - contain Ag- and CeO_2-ENMs in combination with several additives. These particles were selected because of their frequent use based on their bactericide activity (Ag-ENMs) or their UV-stability (CeO_2-ENM). They also represent two groups of ENMs with different solubility: while Ag-ENMs are more soluble, CeO_2-ENMs are considered rather insoluble and biodurable. To address nanoscale effects, respirable ENM sizes of < 100 nm, ~ 200 nm in addition to microsized particles were tested. Because surface active substances are sometimes used to alter the spray behavior, the influence of two perfluorinated silanoles on the ENM toxicity is being tested exemplarily.

The mentioned formulations were analyzed in regard to any alterations on the ENM characteristics before aerosolization and also after spraying onto textiles in order to simulate an impregnation process. Single particle inductively-coupled plasma mass spectrometry (spICPMS) and dynamic light scattering (DLS) were used for analysis in solution. For analysis of sprayed samples, time-of-flight secondary ion mass spectrometry (ToF-SIMS) as well as laser ablation (LA)-ICP-MS were applied.

First results indicate alterations induced in the ENM characteristics regarding size distribution and their dispersion stability by the different formulations. Time-resolved sp-ICP-MS analysis shows decreasing NP sizes for some ENM-formulations.

Using LA-ICP-MS of sprayed textiles, a distinction between different pre-treatments of textile samples could be seen in regard to ENM agglomeration after aerosol application onto these textiles. Using ToF-SIMS analysis penetration depth of applied ENMs to about 1 µm into the textile could be proofed and an aggregation size between 100 nm and 1 µm was recorded whereas the ENMs emitted from the source were sized below 100 nm.

This work is supported by SIINN ERA-NET, which is funded under the ERA-NET scheme of the Seventh Framework Program of the European Commission, Research Directorate - General, Grant Agreement No. 265799, and the German Federal Ministry of Education and Research.

The Basics of Taylor Series Expansion Method of Moment for Brownian Coagulation. MINGLIANG XIE, *Huazhong University of Science and Technology*

In this paper, we will introduce the new development of Taylor series expansion method of moment (TEMOM) for Brownian coagulation, such as the error estimation of TEMOM, the asymptotic solution of TEMOM, and the physical constraint of Brownian coagulation, etc.

These results will help us in understanding the Brownian coagulation and population balance equation.

4AM.2

Effects of Airway Surface Roughness on Local Particle Deposition in Subject-Specific Tracheobronchial Trees. YU FENG, Xiaole Chen, Jianan Zhao, Arvind Santhanakrishnan, *Oklahoma State University*

Computational Fluid-Particle Dynamics (CFPD) models are useful are useful and efficient to understand inhaled aerosol dynamics in human respiratory systems. Crucial to such models is the accuracy of predicting particle depositions. Reconstructed from CT/MRI scanned data, subject-specific human airway configurations are widely used in computational lung aerosol dynamics research. Smoothing the airway surfaces is inevitable during this process. However, the smoothing criteria used are inconsistent among research groups, which may lead to errors in particle deposition results. To investigate the roughness effect and enhance the reliability of the CFPD model, this research simulated the transport and deposition of inhaled particles in 3 tracheobronchial trees reconstructed from the same CT data for a healthy subject with different smoothing intensities. The inhalation flow rate ranges from 30 L/min to 120 L/min, and the particle size is from 50 nm to 10 µm. Numerical results indicate that improper smoothing process will underpredict particle deposition fractions up to 50% in the trachea, which is due to the underestimated turbulence fluctuation effect on particle deposition. In contrast, it is interesting to notice that the roughness effect on particle depositions from Generation 2 (G2) to Generation 6 (G6) is negligible. In conclusion, smoothing process has a significant impact on laminar-to-turbulence transition and local turbulence intensity, thereby influencing particle deposition result variations in the trachea. To employ a proper smoothing process to reconstruct the 3D lung airway geometries for *in silico* studies, it is necessary to accurately measure the airway surface roughness considering the presence of mucus layers. To build a more accurate and realistic *in silico* model for lung aerosol dynamics research, a generalized and unified guideline of the smoothing procedure will be developed based on the extensive intersubject variability studies among virtual population groups with statistical robustness.

Development and Experimental Validation of Coupled Flow-Aerosol Dynamics Model for a Glowing Wire. KUNAL GHOSH, S.N. Tripathi, Manish Joshi, Y.S. Mayya, Arshad Khan, B.K. Sapra, *IIT Kanpur*

We have developed a CFD coupled aerosol microphysics model in context of aerosol generation from a glowing wire. The governing equations can be solved implicitly for mass, momentum, energy transfer along with aerosol dynamics. The computationally efficient framework can simulate temporal behavior of total number concentration and number size distribution. This formulation uniquely couples standard K-Epsilon scheme with boundary layer model with detailed aerosol dynamics through residence time. This model uses measured temperatures (wire surface and axial/radial surroundings) and wire compositional data apart from other usual inputs for simulations. The model predictions show that bulk fluid motion and local heat distribution can significantly affect the aerosol behavior when buoyancy effect in momentum transfer is considered. Buoyancy generated turbulence was found to be affecting parameters related to aerosol dynamics and transport as well.

The model was validated by comparing simulated predictions with results obtained from six controlled experiments performed with a laboratory made hot wire nanoparticle generator. Condensation particle counter (CPC) and scanning mobility particle sizer (SMPS) were used for measurement of total number concentration and number size distribution at the outlet of reactor cell during these experiments. Our model-predicted results were found to be in reasonable agreement with observed values.

The developed model is fast (fully implicit) and numerically stable. It can be used specifically for applications in context of behavior of aerosol particles generated from glowing wire technique and in general for other similar large scale domains. Incorporation of CFD in aerosol microphysics framework provides a realistic platform to study natural convection driven systems/ applications. Aerosol dynamics sub-modules (nucleation, coagulation, wall deposition) have been coupled with Navier Stokes equations modified to include buoyancy coupled K-Epsilon turbulence model. Coupled flow-aerosol dynamics equation was solved numerically and in implicit scheme. Wire composition and temperature (wire surface and cell domain) were obtained/measured, to be used as input for the model simulations. Model simulations showed significant effect of fluid properties on the dynamics of aerosol particles. The role of buoyancy was highlighted by observation and interpretation of nucleation zones in the planes above the wire axis. The model was validated against measured temporal evolution, total number concentration and size distribution at the outlet of hot wire generator cell. Experimentally averaged and simulated total number concentrations were found to match closely, barring values at initial times. Steady state number size distribution matched very well for sub 10 nm particle diameters while reasonable differences were noticed for higher size ranges. Although tuned specifically for the present context (i.e. aerosol generation from hot wire generator), the model can also be used for diverse applications e.g. emission of particles from hot zones (chimneys, exhaust), fires and atmospheric cloud dynamics.

Calculating Wet Deposition and Aerosol Sizes Sensitivities within a Lagrangian Particle Dispersion Code. LI KAIBO, Xu Xuefeng, *China Academy Of Engineering Physics*

This paper describes an investigation into the uses of first-order, local sensitivity analysis in a Lagrangian dispersion code. The goal of the project is to gain knowledge not only about the sensitivity of the dispersion code predictions to the specific input parameters of interest, but also to better understand the uses and limitations of sensitivity analysis within such a context. The dispersion code of interest here is RATRANS, which is used for modeling emergency release scenarios in nuclear accident. Monte Carlo and ensemble techniques are available in RATRANS. Sensitivity analysis is being explored as a means to gain an understanding of the contribution to uncertainty from certain types of input parameters. As a first step, first-order sensitivity analysis was implemented within the precipitation-scavenging module of RATRANS. This module is logically split from the remainder of the dispersion calculation, so the sensitivities may be explored without concern about parameter and computational dependencies, and the linearization implicit in the formulation is acceptable. The general goals of the project are: To understand the sensitivity of RATRANS predictions of precipitation scavenging (wet deposition) to the rain rate and aerosol particle size; To explore the advantages and limitations of first-order sensitivity analysis within a Lagrangian dispersion framework; To gain the understanding necessary to plan a more comprehensive uncertainty analysis project for the RATRANS suite of codes.

Effects of North California Wildfire in October 2017 on Air Quality and Human Health. FENGLIN HAN, Hongliang Zhang, *Louisiana State University*

The October 2017 Norther California Wildfires were a series of over 250 wildfires across the state of California, resulting in severe environmental and economic loss. This study aims to determine transport of and effects of wildfire emissions based on observed data and chemical transport model. The observational data of meteorology and air pollutants including fine particulate matter (PM2.5) are obtained from California Air Resources Board (ARB) sources. Six stations under direct impact with available PM2.5 data were selected. The Community Multiscale Air Quality (CMAQ) model (v5.2) is also applied with anthropogenic emissions from the National Emissions Inventory (NEI) 2014 using the Sparse Matrix Operator Kernel Emission (SMOKE) model (version 4.5). The fire inventory from National Center for Atmospheric Research (NCAR) is used for emissions of wildfires. Spatial and temporal variations wildfire related air pollutants will also be analyzed and contributions of the wildfires will be quantified. The health and economic effects of the wildfires will also be estimated. This study can provide important information for wildfire-related air quality issues and future health studies.

Coarse, Fine and Ultrafine Particles of Sub-urban Continental Aerosols. DRAGANA ĐORđEVIć, Jelena Đuričić-Milanković, Ana Pantelić, Srđan Petrović, Andrea Gambaro, *CEEC – ICTM, University of Belgrade*

The first investigation of size-segregated sub-urban aerosols from the continental part of the Balkan peninsula in 11 fractions in the range of $0.0085 < D_p < 16$ µm was performed from March 2012 to December 2013. Aerosols were measured at the Zeleno Brdo observatory (44° 78' 61" N, 20° 52' 22" E – 243 m above sea level), which is the highest point near Belgrade on its eastern edge, surrounded by wooded vegetation, with rural areas on its southern parts and urban areas on its north-western part. About 70% of total aerosols are fine particles, belonging especially to the PM0.53–1.06 fraction which is more intensive in the winter period. In this work, we applied tests of probability function models, for three distributions: normal, log-normal and three-parameter Weibull, by comparing expected and observed values. This model offered us the possibility to assess whether it is the dominant emission source in the vicinity of the measuring point or it is distant. Results of this test could be a significant supplement to existing multivariate mathematical models for source apportionment for more accurate estimation of the origin of emission sources, offering information on their position relative to the investigated area (local, regional or remote). The dependence of particle concentrations for each fraction investigated versus meteorological parameters was determined.

Consideration of Wildfires as a Source of Airborne Mineral Dust - a Model Approach.

ROBERT WAGNER, Kerstin Schepanski, Michael Jähn, *Leibniz Institute for Tropospheric Research*

Wildfires, like biomass burning, are a very common phenomenon in semi-arid regions nearly all over the world. Investigations of smoke plumes originating from such wildfires found significant fractions of mineral dust and crust-related minerals within these plumes – raised by strong turbulent winds related to the fire. Since wildfires are not considered as a source of mineral dust in aerosol models so far, a better understanding of the processes, which drive fire-related dust emission, is required.

Therefore, high resolved Large-Eddy Simulations (LES) with the All Scale Atmospheric Model (ASAM) were performed to investigate the impacts of wildfires on the near-surface wind pattern. The analysis of fire-related wind pattern is crucial since the emission of mineral dust is a threshold problem, which means that an efficient mobilization of mineral dust particles requires wind velocities above a certain threshold. The influence of different fire properties (intensity, size, and shape) and different atmospheric wind regimes on the dust emission potential is investigated.

The wind fields derived from the LES fire simulations were coupled with an offline dust emission model to calculate the emission fluxes in dependency on the fire properties and the ambient atmospheric conditions. The gained results can be used to estimate typical values of the emitted amount of mineral dust during wildfires, which can be applied for the development of a parameterization of fire-driven dust emission. With that, an estimation of the importance of the process on a continental scale in relation to other types of mineral dust emissions is possible.

Predicting Atmospheric Gaseous and Particulate Phase PCDD/F Concentrations Using PM2.5 Data and Gas-Particle Partitioning Models of PCDD/Fs. Rong Zhao, Kangping Cui, Weiwei Wang, Lin-Chi Wang, Ping Yan, WEN-JHY LEE, *National Cheng Kung University*

In this study, the data of PM2.5 in Handan City and Kaifeng City, China from 2015 to 2017 were obtained from Environmental Monitoring Website. The total PCDD/Fs-WHO2005-TEQ concentrations in ambient air were predicted by using two established equations for proportional relationships between PM10 and PCDD/F mass concentrations. The obtained total PCDD/Fs-WHO2005-TEQ concentrations in Handan city in spring, summer, autumn and winter were 0.100, 0.058, 0.087, and 0.127 pg WHO2005-TEQ m–3, respectively. The averaged total PCDD/Fs-WHO2005-TEQ concentration in Handan (0.093 pg-WHO2005-TEQ m–3) was 1.3 times of magnitude higher than that in Kaifeng (0.073 pg-WHO2005-TEQ m–3) due to higher consumption of heating coal and atmospheric inversion in winter. Furthermore, AQI index could be used to predict the level of total PCDD/Fs-WHO2005-TEQ in ambient air through regression equation. The R2 in 2015, 2016 and 2017 were 0.929, 0.921 and 0.876, respectively.

Taylor-series Expansion Method of Moments for Resolving Aerosol Dynamics. MINGZHOU YU, Yueyan Liu, *China Jiliang University*

The study on aerosol dynamics processes, such as formation of nano/microscale aerosol particle and its subsequent growth in quiescent or evolving flows, has received much attention from both chemical engineering and atmospheric environment communities[1]. The suitable theoretical method for resolving aerosol dynamical processes is widely known as population balance modelling (PBM), which is on basis of solving the population balance equation (PBE) in terms of particle number concentration. The study on the solution of the PBE has undergone rapid development in last several decades. In this talk, the development of methods of moments for resolving aerosol dynamics widely used in the community of air environment, especially the Taylor-series expansion method of moments will be reported; the emphasis will be placed on the optimization of type of moment sequence, selection of Taylor series expansion point, optimization of an order of Taylor series expansion, and selection of terms for Taylor series expansion of the Taylor-series expansion method of moments[2-6].

Towards a Coarse-Grained Model of Nano-Particle Agglomeration. MILENA SMILJANIC, Andreas Kronenburg, Rudolf Weeber, Christian Holm, *University of Stuttgart*

The agglomeration of nano-particles plays an important role in many industrial applications, such as particle flame synthesis and spray-drying, where the structure of the agglomerates strongly affects final product characteristics. The process itself consists of two steps: (1) nano-particles collide due to their relative velocities caused by Brownian motion and/or turbulent flow, and (2) they adhere and form aggregates. Detailed models use Langevin Dynamics to track the movement of each particle and compute particle collisions and particle-particle interactions individually, as it is reported in the literature. More recent work investigates the influence of turbulent motion on aggregates' growth and the resulting aggregate morphology. Numerical simulations were, however, limited to rather low numbers of particles (up to 4 million particles) and rather dense particle loadings. This limited the statistics and prevented long simulation times.

The simulation of larger systems will require some simplifications of the modeling process. Here, we develop a coarse-graining approach for the agglomeration of nano-particles and clusters, covering both primary particles of the size of few nanometers to agglomerates that are several orders of magnitude larger. Coarse-graining involves the replacement of parts of the clusters by "representative" particles of (representative) spherical shape. Due to the sparse nature of agglomerates, two spheres that envelop their respective agglomerates could intersect, but the agglomerates that they represent would not necessarily touch and stick. This approach allows not only for collisions on the surface, but also for the particle-cluster or cluster-cluster penetration, based on the calculated collision probability as a function of compactness of the underlying aggregates and of the overlap of the two coarsened spherical particles.

For the calculation of collision probability functions, besides usual agglomerate's morphology characteristics such as number of particles (N), radius of gyration (R_g) and fractal dimension (D_f), we additionally used agglomerate's maximum radius (R_{max}). Assuming random aggregate orientation, we introduce a model of concentric spherical shells, placed at the aggregate's center of mass, with minimal shell radius and shell width equal to the single particle diameter and the maximum shell radius equal to the aggregates maximum radius, respectively. Identical clusters randomly rotated are then shot towards the aggregate, and collisions between their respective particles are saved as hits (n_{hit}) for the corresponding cluster shells. On the contrary, penetration of the tested clusters through shells without detecting any collision are accounted for misses (n_{miss}). For each cluster there are conducted N=3000 simulations and averaged within several cluster groups, over 100 clusters for each cluster group. This study examines aggregates of following characteristics: Rg=(3,5,7) and Df=(1.6,2.0,2.4).

Distance dependent collision probabilities ($P_{coll,i}$) have been calculated as

$P_{coll,i}=n_{hit,i/}(n_{miss,i}+n_{hit,i})$.

As results show, along the interaction radius collision probability function is strongly affected by the aggregate fractal dimension and radius of gyration, slightly varying within relatively confined parameter ranges. In addition to it, results on cluster-cluster collision probabilities are used in coarse-grained simulations as determining parameter for creating bonds between colliding coarsened particles and their further growth, as well as for modelling of cluster-cluster interactions.

4AM.11

High Resolution Chemical Transport Modeling of Ultrafine Particles over Pittsburgh. SHAYAK SENGUPTA, Pablo Garcia, David Patoulias, Provat Saha, Wei Ma, Christopher Tessum, Iannis Kioutsioukis, Sean Qian, Spyros Pandis, Inês Azevedo, Peter Adams, *Carnegie Mellon University*

Ambient ultrafine particles (UFPs), solid or liquid particles in the atmosphere with diameters less than 100 nm, pose poorly understood human health impacts relative to well-understood impacts of $PM_{2.5}$. Numerous studies have documented health effects related to roadway proximity, with UFP emissions from traffic as a possible culprit. However, high spatial variability and the lack of widespread monitoring complicate exposure quantification of UFPs. The goal of this work is to develop and evaluate high resolution (1 km) chemical transport model (CTM) simulations to quantify UFP concentrations as a step towards quantifying UFP exposure in an urban area. This study uses PM-CAMx-UF to predict UFP concentrations in the Pittsburgh metropolitan area at 1 km spatial resolution for multiple seasons in 2016 and 2017. PM-CAMx-UF is a state-of-the-science CTM which simulates the production and destruction of UFPs in the atmosphere by explicitly tracking both particle number and mass concentrations. Model inputs include traffic emissions at 1 km resolution, spatially resolved using a traffic model for Pittsburgh. Simulations test the CTM's ability to accurately predict UFP concentrations and understand which sources impact particle number concentrations. Furthermore, we test simulations at 4 km, 12 km and 36 km resolutions to identify and compare the amount of spatial variability in UFP concentrations resolved by the CTM. We evaluate our model predictions with a distributed, intraurban network of observation sites which includes stationary water-based condensation particle counters, scanning mobility particle sizers, and beta attenuation monitors to monitor both particle mass and number concentrations in traffic-heavy and non-traffic-heavy locations. Mobile van sampling throughout Pittsburgh complement stationary observations to evaluate model performance. In addition to showing model performance evaluation, use of model results to predict population exposure will show the impact of model resolution on quantifying UFP and PM2.5 exposure. Any nonzero correlation between predicted total particle number concentration and $PM_{2.5}$ mass concentration suggests potential exposure confounding in long-term health impact quantifications.

4AM.12

Simulation of SOA Formation of Monoalkyl-substituted Benzenes in the Presence of SO2 under Different NOx Levels Using the UNIPAR Model.

CHUFAN ZHOU, Myoseon Jang, *University of Florida*

The secondary organic aerosol (SOA) formation from the photooxidation of hydrocarbons is influenced by the concentration of coexisting tracers such as NOx and SO2, the meteorological conditions (humidity and temperature), and atmospheric aging. SOA contributes significantly to total fine particulate matter, and yet the prediction of SOA formation remains inadequate. Our laboratory's recent research efforts have improved the state-of-the science-art via the development of the Unified Partitioning-Aerosol Phase Reaction model (UNIPAR), which utilizes explicit gas chemistry to predict SOA formation from multiphase reactions. The UNIPAR model vastly improved the accuracy of chamber generated SOA mass predictions. The oxidized semivolatile organic compounds predicted using gas-phase explicit mechanisms are lumped into 8-volatility. Each volatility group is further classified into 6-groups based on their emerging chemistry in the aerosol phase. Glyoxal (Gly), methylglyoxal (MGly), and IEPOX are separately treated in UNIPAR because they are known to significantly contribute to SOA formation. The UNIPAR model features the dynamic product stoichiometric coefficients (51 lumping groups) that can change with atmospheric aging and NOx levels. Additionally, thermodynamic parameters (activity coefficients of lumping groups) in the model are also dependent of the aging process and NOx levels. The impact of the aging process on the model parameters was dynamically treated using the quantity of typical radical species (i.e., HO2 and RO2), which are commonly predicted in most chemical mechanisms in air quality models. Among urban hydrocarbons, monoalkyl-substituted benzene are important precursors to form SOA. In this study, the feasibility of the UNIPAR model is demonstrated to SOA formation from various monoalkyl substituted aromatic SOA against chamber data from University of Florida Atmospheric Photochemical Outdoor Reactor (UF-APHOR). The lumping base UNIPAR, constructed using explicit mechanism, enables the flexible treatment of multiphase partitioning and aerosol chemistry (i.e. oligomerization in organic phase, acid-catalyzed reactions in inorganic aqueous phase, and OS formation). As a result, UNIPAR is able to improve the ability to accurately estimate SOA mass, which is under-predicted by current regional models.

4AM.13

Effect of Dispersion & Coagulation Parameters on the Survival Fraction of Aerosol Particles Released from Puffs and Plumes.

Tanmay Sarkar, S. Anand, Y.S. MAYYA, *BARC*

The concept of particle survival fraction finds important application for estimating the contribution of localized emission sources to the persisting aerosol background in the atmosphere. In recent times, this concept has found an important application in the area of geo-engineering proposals in order to slow down global warming, in which light scattering aerosol plumes are supposed to be deliberately released from ships to the clouds to enhance marine cloud brightening. As the particles releases from highly inhomogeneous sources, they would undergo significant coagulation during their dispersal to form background aerosols. An effective way of quantifying this effect is to model their survival fraction by combining coagulation equation with dispersion equation. A major difficulty arises while combining aerosol microphysical processes with dispersion equation, particularly coagulation process as it leads to non-linear integro-differential equation. Several approaches have been developed by various authors in the past to solve the governing equation for particles undergoing simultaneous dispersion/Brownian diffusion and coagulation, such as analytical solutions to special cases (Simons, 1996), expanding plume models (Turco and Yu, 1999). The diffusion–coagulation equation that governs the evolution of a spatially inhomogeneous aerosol puff and plumes is solved by Anand and Mayya (2011). This model is extended to geo-engineering problems (Anand and Mayya, 2015). To make the solution methods or numerical computations simpler, several approximations on 1) particle size distribution, 2) coagulation kernel, and 3) dispersion process are made.

In the present study, we examine the effect of these parameters on the survival fraction of particles in a spherical puff through exact numerical calculations. The numerical program can consider any initial particle size distribution such as lognormal, exponential, etc., and coagulation kernels such as free-molecular and Fuchs kernels, which can handle fractals also. The diffusion coefficients for the particles released from the point sources are generally expressed as either space- or time-dependent variables. The study demonstrates that the survival fraction will be lower for an initial polydisperse spectrum as compared to a mono-disperse spectrum. The effect of polydispersity is further studied by varying the parameters of initial size distribution (CMD and GSD). The inclusion of Fuchs kernel and non-constant dispersion coefficient in the numerical program affects the evolution of particle survival fraction compared to the constant kernel case. These realistic simulations finally determine the fraction of emitted particles survived due to combined action of coagulation and atmospheric dispersion. This model is proposed to compute source emission correction factor for various indoor emission sources to estimate effective number concentration to the indoor background environment and then to global aerosol background.

Aerosol Impaction under High Knudsen Number, High Mach Number Conditions for Applications in Additive Manufacturing.

CHENXI LI, Bernard Olson, Christopher Hogan Jr., *University of Minnesota*

Aerosol deposition has emerged as a novel additive manufacturing (AM) method for surface coating and thin film production. Though inertial impaction is typically the deposition mechanism, AM based deposition functions in a very different regime from traditional sampling based impactors. Specifically, the AM process involves accelerating supermicrometer particles (rarely submicrometer particles) with a high-speed carrier gas leading to particle at supersonic speeds with the potential plastic particle deformation on the substrate. It is generally acknowledged that the instantaneous particle speed upon impaction is critical to controlling coating/film properties such as porosity, and mitigating particle bounce during deposition. Therefore, to achieve desirable particle impaction speed, converging-diverging nozzles (i.e. de Laval nozzles) are frequently used to accelerate particles.

Though considerable effort has been devoted to simulation of particle trajectories as well as impaction speed, some critical aspects of using de Laval nozzles for particle acceleration are yet to be fully understood. This presentation discusses two issues related to this process. The first issue concerns drag force exerted on particles by carrier gas. As particles traverse through the nozzle, rapid gas rarefication and densification (due to a shock) can lead to particle Knudsen number (Kn) variations by as much as ~100, ranging from the free molecular to continuum regimes. In addition, due to gas stagnation close to substrate or insufficient particle acceleration, particle Mach numbers (Ma, based on relative speed of gas and particles) can exceed unity with potential shockwave formation close to the particle surface. Simulation of particle trajectories, therefore, requires a drag law that is valid for a wide range of of Kn and Ma. The first part of this presentation consists of summary and comparison of the existing drag laws with a focus on range of validity, and proposal of a new drag law based on direct simulation Monte Carlo valid for the range $0 < Kn < \infty$ and $0 < Ma < 3$.

The second issue relates to how operating conditions of the converging/diverging nozzle influences particle impaction speed. Specifically, two factors are discussed: (1) particle size, (2) upstream/downstream pressure of the nozzle. Given other operating conditions, we show that impaction speed is a function of particle size, with an optimum particle size with the maximum impaction speed for a given nozzle geometry. As to upstream/downstream pressure, our simulations demonstrate they change the shock wave structure and have a significant effect on deceleration of nanosize particles by changing the gas pressure close to the substrate.

Quantifying and Valuing the Role of UK Vegetation in the Removal of Particulate Matter. EIKO NEMITZ, Laurence Jones, Massimo Vieno, Daniel Morton, Carnell Ed, Stefan Reis, Ian Dickie, Philip Cryle, Holland Mike, *Centre for Ecology and Hydrology*

Air pollution presents a major risk to human health, resulting in premature deaths and reduced quality of life. Vegetation can play a role in reducing concentrations of air pollutants, but estimates of the service that vegetation provides are highly variable.

The majority of methods used to calculate pollution removal are driven with static concentrations and therefore ignore the feedback of removal on concentrations, and interactions with wet deposition processes and between compounds.

In this study we applied an atmospheric chemistry and transport model (EMEP4UK) to calculate the amount of pollutant removal in the UK by current vegetation for $PM_{2.5}$, but also gaseous pollutants (NO_2, NH_3, SO_2, O_3) by comparing a model run with current landcover to a baseline scenario in which vegetation was replaced by bare soil. From these data we calculated the health benefits from the changes in pollutant concentrations (i.e. change in exposure) induced by the additional pollution removal by the vegetation.

Results show that current UK vegetation as a whole reduces concentrations of $PM_{2.5}$ by around 10%, far greater than in previous studies. The economic value of the health benefits are substantial: £1 billion in avoided health costs estimated for 2015, resulting from 1900 avoided deaths, 27,000 avoided life years lost, 5,800 fewer respiratory hospital admissions and 1,300 fewer cardiovascular hospital admissions.

We also show that the benefits do not always occur in the same location as the pollutant removal. In other words the benefits, defined in terms of reduced pollutant concentrations, are also transported in the atmosphere.

4AM.18

Prediction of the Chamber Wall Process of Gaseous Semivolatile Organic Compounds Using a Linear Solvation Energy Relationship. HUANHUAN JIANG, Myoseon Jang, Sanhee Han, *University of Florida*

The chamber wall process of gaseous and semivolatile organic compounds has been known to significantly influence studies of secondary organic aerosol (SOA) formation. For example, the wall process of gaseous semivolatile organic compounds leads considerable underestimation of SOA yields (e.g., 30% for toluene SOA) and furthermore affects the credibility of the predictive SOA model derived using chamber data. In this study, a mathematical model is built to predict the of uptake coefficient of a gaseous semivolatile organic compound by the integration of the deposition kinetics of organic compounds with a Linear Solvation Energy Relationship (LSER). The deposition process of organic compounds is approached using a conservation balance via on- (adsorption) and off-kinetic mechanism (desorption) between the gaseous phase and the chamber wall phase. The adsorption rate constant (k_{on}) of organic compounds is processed using a conventional mass transfer process. The desorption rate constant (k_{off}), which is linked to both an off-gassing rate constant and the gas-wall partitioning coefficient of an organic compound, *i*, ($K_{\mathrm{i,wall}}$), is semiempirically predicted by fitting the measured decay rate of compound *i* to the thermodynamic physicochemical parameters based on LSER. Various model compounds (i.e., long-chain deuterated alkanes, alcohols, carboxylic acids, and carbonyls, substituted phenols) are introduced into the large outdoor smog reactor (UF-APHOR chamber). The deposition rate constants of these compounds are measured using the traditional denuder sampling integrated with a gas chromatography-mass spectrometer (GCMS) in the course of a 12-hour wall-loss process. The resulting deposition rate constants are applied to the derivation of the model. Our recent exploratory data proved that the deposition process was well-predicted using the newly derived LSER base model. In this study, the resulting wall process model will be applied to the estimation of SOA yields and improve the quality of explicit SOA models (i.e., UNIPAR).

4AM.19

3-D Numerical Study of Linear Slot Virtual Impactor. WONYOUNG JEON, Hyunwoo Lee, Youngjin Seo, *Kumoh National Institute of Technology*

Virtual Impactor (VI) is used to classify particles into two sizes or to concentrate them to increase the concentration of particles. The basic principle of VI is to take advantage of the inertia that particles get through the accelerating nozzle. The most important point when designing a VI is to minimize the loss of particles (deposition due to collisions with walls). Losses at the wall has an adverse effect on VI performance. This study focuses on developing and optimizing the VI that operates at the flow-rate of 150 LPM. Target cut-point is 1 micrometer. The research is conducted for three steps. First, we numerically optimize the 2-D LSVI (Linear Slot Virtual Impactor). Second, we characterize 3-D geometry by simulating 3-D LSVI by selecting several revamped 2-D models. The particle simulation for the 3-D LSVI will be carried out at particle diameters in the size range of 0.1 to 15 micrometers. Finally, experiments will be conducted to verify the optimization model using fluorescent particles (0.3 to 10 micrometers). Experiments will be conducted in a closed-loop system. In this paper, we present how the critical geometry factors change the performance of a VI through 3-D simulation. In addition, we will present preliminary experimental data out of the 3-D model.

Numerical Investigation on Artificial Cloud Seeding as a Means of Precipitation Enhancement. ALI AFZALIFAR, Juha Tonttila, Kudzotsa Kudzotsa, Tomi Raatikainen, Harri Kokkola, Sami Romakkaniemi, *Finnish Meteorological Institute*

Globally, about 1.2 billion people lack access to water and more than twice this number suffer from inadequate sanitation and seasonal water scarcity. Given the present consumption rate of water, this problem will only become worse. Cloud seeding, in form of artificial emission of large particles from ground or a flying aircraft, is thought to provide a promising solution to this problem particularly in regions with low rainfall. Over the years, although several studies have corroborated the positive correlation between the cloud condensation nuclei, emitted through cloud seeding, and precipitation formation, the confidence in the effectiveness of cloud seeding is still far from absolute. In the present work, the large eddy model UCLALES along with the aerosol module SALSA is applied to study aerosol-cloud microphysical processes at a cloud-resolving scale. The model UCLALES-SALSA employs a detailed sectional microphysical scheme which represents the size distribution of aerosol, clouds and precipitation in terms of number of fixed size sections. The latest version of the model benefits from schemes for both natural and artificial aerosols emissions, thus it provides a powerful means to predict the effects of cloud seeding on precipitation. Moreover, the experimental study on the effects of artificial emission of giant cloud condensation nuclei on precipitation, performed by Jung et al. (2015; ACP), is used to validate the modelling results in this work.

A Simulation Tool to Understand the Chemistry of Hexavalent Chromium in Airborne PM at pH 5 and pH9. MEHDI AMOUEI TORKMAHALLEH, Dinara Konakbayeva, Marios Fyrillas, Mirat Karibayev, *Chemical and Aerosol Research Team, Nazarbayev University*

Chromium is found in the atmosphere in two stable oxidation states, trivalent chromium (Cr(III)) and hexavalent chromium (Cr(VI)). Cr(III) is an essential element for living organisms, mainly involved in the control of lipid and glucose metabolism. Conversely, Cr(VI) is a toxic element, and based on the exposure duration it causes adverse health effects such as perforation of the nasal septum, asthma, bronchitis, pneumonitis and lung cancer. Insoluble forms of Cr(VI) might be more toxic than soluble compounds. Soluble Cr can enter the blood and be excreted or be converted to Cr(III) in the blood stream. Animal studies demonstrated that slightly soluble and highly insoluble Cr(VI) particles such as the chromates of zinc, lead, strontium, barium, and sintered calcium consistently induced a tumor response, albeit with variable efficacy. Thus, it is imperative to investigate the soluble and insoluble fractions of Cr in the atmosphere to better understand its health effects. To obtain a more complete picture of atmospheric aqueous Cr speciation, Cr chemistry in the presence of a mixture of atmospheric oxidants and reductants including ambient PM matrix and dissolved gases needs to be investigated. Nevertheless, soluble and insoluble forms of the Cr(III) and Cr(VI) were not investigated in previous modeling studies. Currently, Cr(VI) sampling involves collecting PM on a filter at pH 9 and is integrated with wet chemical analysis. PM on the sampled filters is extracted using an alkaline or acidic solution that is then analyzed by Ion Chromatography (IC) or a combination of IC and ICPMS, respectively. However, wet analysis procedures may not extract the insoluble Cr(VI) and thus, may underestimate atmospheric Cr(VI) concentrations. Understanding the soluble and insoluble forms of Cr in the atmosphere using modeling studies will assist in better designing and integrating Cr(VI) sampling and analysis systems. The objective of this study was to develop a conceptual model for the aqueous chemistry of the atmospheric Cr where Cr is a non-limiting reactant, and to implement this model to better understand the soluble and insoluble forms of Cr(III) and Cr(VI) compounds under atmospheric and sampling conditions. This model is also applicable to locations where Cr emitting industries exist. The results of the present investigation will be helpful in developing an analytical method to quantify total Cr (soluble and insoluble) species in the atmospheric PM. Field measured concentrations of atmospheric species were utilized as model input in this study. The dominant form of Cr(VI) in the pH 5 solution was found to be Cr2O7 2-. At pH 5 chromate was produced by the dissolution of Na2CrO4(s) and K2CrO4(s) available in the solid core, but a considerable portion of the CrO4 2- precipitated as (NH4)2CrO4(s), CaCrO4(s), BaCrO4(s) and PbCrO4(s). Cr(OH)3 was found to be soluble, and the insoluble form of Cr(III) was Cr2(SO4)3. Conversion of Cr(VI) to Cr(III) was higher than the conversion of Cr(III) to Cr(VI). The simulation results agree with the field measurements near Cr industries. At pH 9, CrO4 2- was the dominant soluble form of Cr on the sampling filter while (NH4)2CrO4, CaCrO3, BaCrO4, PbCrO4 were the dominant form of insoluble Cr(VI). Reduction of Cr (VI) to Cr (III) was higher than the oxidation of Cr (III) to Cr (VI).

4AM.23

Evolution of PM Components in Europe over the 1990-2010 Period in the Framework of the Eurodelta-Trends Exercise. GIANCARLO CIARELLI, Augustin Colette, Matthias Beekmann, Mark Theobald, Peter Wind, Camilla Andersson, Florian Couvidat, Astrid Manders-Groot, Mihaela Mircea, Maria Teresa Pay, Valentin Raffort, Svetlana Tsyro, Kees Cuvelier, Mario Adani, Bertrand Bessagnet, Robert Bergstrom, Gino Briganti, Andrea Cappelletti, Massimo D'isidoro, Hilde Fagerli, Yelva Roustan, Marta Vivanco, *LISA*

Recent studies have investigated the changes in particulate matter (PM) concentrations over the past decades in Europe. However, only a few have investigated the evolution of the individual PM components, i.e. inorganic and organic phases, following the implementation of emission reduction strategies. The trends in PM components might differ as a result of the different chemical regimes in different European regions and the non-linear response of PM to changes in precursor emissions. Thus, understanding how the chemical composition of PM has varied during the last decades could provide more insight for future air quality legislation.

In the framework of the EURODELTA-Trends (EDT) modeling exercise, several Chemical Transport Models (CTMs) were applied for the 1990–2010 period in order to investigate air quality changes in Europe due to the implementation of emission reduction strategies. A common anthropogenic emission dataset was used by the modeling teams (i.e. NO_2, SO_2, HN_3 and non-methane VOCs) based on estimates from the Greenhouse gases and Air pollution Interactions and Synergies (GAINS) model. Model simulations were conducted at 0.25° and 0.4° resolution in latitude and longitude, respectively, with a domain extent from 17° W to 39.8° E and from 32° S to 70° N. Five CTMs have provided air quality estimates for a 21 year period (i.e. CHIMERE, EMEP/MSC-W , MATCH, LOTOS-EUROS and MINNI).

For this study, we combined consolidated long-term air quality measurements of sulfate (SO_4^{2-}), total nitrate (TNO3), total ammonium (TNH4), as well as sulfur dioxide (SO_2) and nitrogen dioxide (NO_2) available for multiple sites in Europe for the 1990–2010 period with output data from the CTMs used in the EDT exercise.

Comparisons between modeled and measured data showed a relatively good agreement between the model ensemble and the measured data. In particular, the faster decline in SO_2 and SO_4^{2-} concentrations in the first decade analyzed (1990–2000) compared with the second one (2000–2010) was well captured by the model ensemble. For TNO3 and TNH4 concentrations, both the measurements and the model ensemble showed rather flat trends for both periods, with larger differences in trend significance occurring at a single station level. The evolution of the modeled secondary organic aerosol (SOA) concentrations were also investigated together with the trends in emissions of biogenic volatile organic compound (VOCs). For the models that provided biogenic emission data, a statistically significant increase in biogenic emissions (i.e. isoprene and monoterpene) was found along with an increase in the relative contribution of biogenic SOA (B-SOA) to the total SOA.

In addition, modeled SOA concentrations were evaluated against positive matrix factorization (PMF) data available during the second decade. Results indicated a systematic under-estimation of the modeled SOA fraction with large differences between the models, most likely due to the different levels of complexity of the SOA schemes.

Comprehensive Organic Emission Profiles for Mobile Sources: Integration of VOC, IVOC, SVOC and Lower Volatility Organics.

QUANYANG LU, Yunliang Zhao, Albert Presto, Andrew May, Tim Gordon, Allen Robinson, *Carnegie Mellon University*

Mobile sources contribute about one-third of anthropogenic organic emissions in the 2014 EPA National Emission Inventory (NEI); they are an important source of POA (primary organic aerosol) and SOA (secondary organic aerosol) precursor gases, especially in urban environments. Traditional emissions inventories account for two types of organics: volatile organic compounds (VOCs) in the gas-phase and particulate matter (PM). However, this is an overly simplistic representation.

We compiled recently published data to create comprehensive model-ready organic emission profiles for gasoline, gas-turbine, and diesel sources. Our source profiles span the entire volatility range, from nonvolatile organic compounds (NVOC) to low-volatile organic compounds (LVOC), semi-volatile organic compounds (SVOC), intermediate-volatile organic compounds (IVOC) and VOC. The overall mass closure of integrated organics to bulk measurement of non-methane organic gases and organic carbon (NMOG+1.2*OC) is 0.83 for on-road gasoline source, and ~1 for on-road diesel source.

The fractions of IVOC and SVOC to the total organic emissions (NMOG+1.2*OC) are consistent within source type: contributing about 4.5% (2.4%-9.6% as 10th to 90th percentile) and 1.1% (0.4%-3.8%) for gasoline engines, 20-27% and 4.5-7.5% for gas-turbine engine, and 52.5% (45.5%-60.0%) and 4.0% (3.0%-4.6%) for diesel engines.

Organic emissions from all source categories have tri-modal volatility distributions. The largest model is ‘fuel’ mode, which contributes 72.6% (66.5%-77.6%) total organic emissions in gasoline, 65.2% (59.8%-79.6%) in diesel exhaust, and 37.5-38.5% for gas-turbine. The ‘fuel’ mode mirrors the trends in fuel volatility. Emissions from each source also has a low-volatility mode, comprised of SVOCs and even less volatile organics, which peaks at a C* of 10 $\mu g\ m^{-3}$. The final mode is the most volatile, peaking at a C* of 10^{10} or 10^{11} $\mu g\ m^{-3}$. It contributes about 25% of the total organics in gasoline and diesel exhaust, and 50-57% for gas-turbine engine exhaust. The composition of this mode is primarily comprised of alkenes and carbonyls.

IVOCs are enriched in the exhaust relative to the fuel, especially for gasoline sources. Sources using more volatile fuel have higher IVOC enrichment factors. Gasoline engine exhaust has a median enrichment factor of 8.5 versus no enrichment for diesel exhaust. Gas turbine exhaust falls in between.

Three approaches are used to parameterize IVOC emission for use in SOA models, which are 1-group, 4-group and source-specific parameterizations. First, using a single lumped group for all sources, we obtained the relative error is ≤20% for gasoline and diesel source, and ≤40% for gas-turbine source, within OA concentration from 0 to 20 $\mu g\ m^{-3}$. Second, when using 4-group parameterization, the relative error is reduced to ≤15% for gasoline and diesel source, and ≤35% for gas-turbine source. Third, by fitting for each source separately, relative error for all sources could be bounded within 10%.

The new profiles predict that IVOCs and SVOC vapors contribute significantly to SOA production, especially for sources using lower volatility fuels. For gasoline sources, IVOCs and SVOC vapors contribute ~80% SOA than tradition VOC precursors. For gas-turbine and diesel sources, IVOCs and SVOC vapors contributions exceeds the SOA production from VOC emissions by a factor of 18 and 38, respectively. Also, the new profiles treat POA as semi-volatile, and they predict that 40%-50% of POA mass evaporates at ambient conditions. There is a large change in the composition of the OA, changing from 50% (traditional) to more than 80% (new) of gasoline OA mass is SOA.

4AM.27

Urban Air Quality Modeling at High Spatial Resolutions. PABLO GARCIA, Peter Adams, Spyros Pandis, *Carnegie Mellon University*

Human activities in dense urban areas produce significant emissions of atmospheric pollutants and their precursors and these have adverse health effects on the exposed population. Emission sources like traffic and restaurants have significant variations at the urban scale. Resolving the pollutant concentration fields and the health impacts associated with these and other sources requires emission inventories, measurements and simulations to be available at high resolutions. A high resolution emission inventory was developed for the city of Pittsburgh and surrounding counties based on the EPA's National Emission Inventory (NEI) for 2011 with novel spatial surrogates to geographically distribute emissions in a grid of 1x1 km cells. This inventory was used to predict gaseous pollutants and speciated particle matter (PM) concentrations with the PMCAMx chemical transport model for the period of the Center for Air, Climate and Energy Solutions (CACES) campaign in Pittsburgh. Model predictions were compared with national speciated PM networks and Aerosol Mass Spectrometer data from the CACES supersite. The predictions were also compared with measurements taken with a mobile laboratory at high spatiotemporal resolution in urban and suburban areas in Pittsburgh. These comparisons were repeated with a baseline simulation using the standard NEI approach. PMCAMx predicts concentrations reasonably well, showing improvement when compared to the standard NEI approach.

4AM.28

Coupled Gas and Particle Phase Modeling of Isoprene SOA Formation. KELVIN BATES, Rebecca Schwantes, John Seinfeld, *California Institute of Technology*

Following the creation of a state-of-science gas-phase isoprene oxidation mechanism, a new module has been developed to simulate secondary organic aerosol (SOA) formation from isoprene oxidation under a wide range of conditions by coupling a reduced version of the gas-phase mechanism to a simplified particle-phase mechanism. The model is prepared in Kinetic PreProcessor (KPP) format for easy simulation of environmental chamber experiments. We present results from a series of simulations of experiments performed in the Caltech environmental chambers investigating SOA yields directly from OH-initiated isoprene and methacrolein oxidation under various [NO], [NO_2], temperature, humidity, and seed aerosol conditions. Both the model and the experiments incorporate SOA formation from isoprene epoxydiols (IEPOX), methacryloyl peroxynitrate (MPAN), and highly functionalized semi-volatile isoprene derivatives. The model code will be made freely available online as part of the existing gas-phase isoprene oxidation mechanism (DOI 10.22002/D1.247).

4AM.29

Modeling the Effects of Central American Fire Emissions on Air Quality in Texas. QIANJIN ZHENG, Min Zhong, *Texas A&M University-Kingsville*

Natural and anthropogenic fires emit the significant number of particles and gaseous air pollutants. Each year during the spring season, large amounts of smoke from the Yucatan Peninsula and southern Mexico transport across the Gulf of Mexico and reach the south-central United States. This long-range transported smoke causes deteriorating air quality periodically in Texas. As anthropogenic emissions continue to decline steadily, the contribution of emissions from long-range smoke will likely increase. This research leverages the Weather Research and Forecasting model coupled with Chemistry (WRF-Chem) to study the impact of fire emissions from Central America on surface fine particle matter ($PM_{2.5}$), aerosol optical depth (AOD), carbon monoxide (CO), and Ozone (O_3) in Texas. The model domain covers multiples states in southern U.S., Mexico, and Central America at 12 km horizontal resolution. The anthropogenic emissions inventory is based on a global emission inventory; the Hemispheric Transport of Air Pollution (HTAP_V2.2) and Fire INventory from NCAR (FINN) is used for fire emissions. The initial and lateral boundary conditions for chemical species are taken from the MOZART global chemical transport model. The gas-phase and aerosol chemistry are represented by the Regional Atmospheric Chemistry Mechanism (RACM) and the Model Aerosol Dynamics for Europe with the Secondary Organic Aerosol Model (MADE/SORGAM), respectively. In-situ ground measurements and satellite observations are applied to evaluate the WRF-Chem model performance in March-May 2013. We find that smoke from Central America spreads across certain areas in Texas and significantly affects the local and regional air quality. Our study indicates that long-range fire emissions should be considered in evaluating the relative effectiveness of local emissions control program.

4AM.30

Climate System Responses to the Interactions between Wildfires and Climate. AOXING ZHANG, Yuhang Wang, Yufei Zou, *Georgia Institute of Technology*

While the effects of climate on wildfires and those of wildfires on climate have been studied in the past, little is known how the feedbacks between wildfires and climate affect the climate system behaviors. For example, large amounts of aerosols released by wildfires change regional climate through direct radiative forcing and aerosol-cloud processes. The resulting regional climate changes also regulate the occurrence frequency, magnitude, and duration of wildfires. Similar interactive processes also take place for fire-induced land surface and vegetation changes. These interactions have not yet been carefully studied because current climate models lack the capability of simulating the interactions between wildfires and climate. We have developed the REgion-Specific ecosystem feedback Fire (RESFire) model and implemented it into the Community Earth System Model (CESM), which allows us to examine the responses of wildfires and climate to their interactions. We find that wildfire-climate interactions due to aerosols tend to decrease the global precipitation, although regional variations in magnitude and sign are large. The western United States, for example, shows a clear drying effect. While the aerosol effects tend to be short-term (days-weeks), the climate responses can be inter-seasonal and interannual. The fire induced land cover changes, the effects of which last much longer (years), also affect the climate system behavior in short term. We examine further the differences of wildfires and climate interactions at present to the future projections based on the RCP4.5 scenario and find that the system responses differ as the climate warms.

4AM.31

Formation of Sulfate during Winter High Pollution Events in Beijing. Peng Wang, Li Wu, QI YING, Jianlin Hu, Hongliang Zhang, *Texas A&M University*

Sulfate is a major aerosol component in severe winter haze events in many areas across China. Debates on the importance of various pathways of S(IV) to S(VI) oxidation, including gas and aqueous reactions as well as heterogeneous reactions have been ongoing without a clear consensus. Recently, the importance of the aqueous phase oxidation by NO2 and by O2 catalyzed by transition metals is being extensively discussed. In this study, we applied a modified CMAQ model to evaluate the contributions of these different pathways to sulfate formation in January 2013 when daily average sulfate concentration reached more than 100 μg m^{-3}. A sulfate formation tracking method based on the source-oriented modeling approach is implemented to track sulfate from different pathways. To have a better understand of the vertical distribution of the sulfate formation rate, the source-oriented approach also keeps track of sulfate formation of different vertical layers. By doing this detailed modeling exercise, we aim to provide more detailed understanding of the sulfate formation processes in the region.

4AM.33

Brownian Diffusion of Nano-Fibers. LIN TIAN, Goodarz Ahmadi, Jiyuan Tu, *RMIT University*

Motion of nanoparticles that are suspended in fluids are dominated by Brownian diffusion – a physical property well understood following Einstein (1905). While theoretical derivation and experimental measurement of the diffusion coefficients for spherical particles are well developed, such information for non-spherical particles are lacking. In this study, the Brownian diffusion of elongated nano-fibers is investigated numerically. Motion of the nano-fiber is resolved by solving the system of equations governing its coupled translational and rotational motion. To isolate the Brownian diffusion from other diffusive forces, test fibers are immersed in an unbounded quiescent fluid where only the hydrodynamic drag and Brownian forces are present. The study allows a close look at the Brownian diffusion of the nano-fibers with respect to the translation, rotation, coupling, and how the rotation affects the particle's macroscopic diffusion properties. Particular attention was given to the rotational relaxation time in determining the non-spherical particle's isotropic and anisotropic diffusive properties. Theoretical and semi-empirical equations are developed to quantify the diffusion coefficients of nano-fibers. The predications are compared with the experimental data, and excellent agreement was obtained. The study opens up new approaches for studying fundamental diffusive processes of nano-particles of complex shapes which are abundant in natural environment.

4AP.1

The Concentrations of Aerosol Surface Area in Fukue Island, Japan, Measured by Diffusion Charging Method. MIHO KIRIYA, Tomoaki Okuda, Ayako Yoshino, Akinori Takami, Indra Chandra, Takafumi Seto, Koji Funato, Kozo Inoue, *Keio University*

Observation of the ambient aerosol surface area concentrations is important to understand the aerosol toxicity because an increased surface area may be able to act as an enhanced reaction interface for certain reactions between aerosol particles and biological cells, as well as an augmented carrier surface for co-pollutants. In this study, the aerosol surface area concentration was measured together with black carbon (BC) and other chemical species such as organic compounds, sulfate, and nitrate on April 2017 in Fukue Island, Japan. The concentrations of aerosol surface area were highly correlated with those of BC, which has relatively large surface area since BC particles are usually submicron agglomerates consisting of much smaller (tens of nanometers) sized primary soot particles. Compared with the concentrations of aerosol surface area in Fukuoka city, those in Fukue Island did not increase at daytime. This was due to low BC concentrations because of small traffic volume in suburban area of Fukue Island. Also, there were some cases which the concentrations of aerosol surface area did not increase even though sulfate concentrations increased. According to the airmass backward trajectories analysis, those low surface area-high sulfate events seemed to be affected by the airmass from East China Sea.

4AP.2

Measurement of the Electrostatic Charging State of Ambient Aerosol Using a Parallel Electrode Plate Device. KENTARO FUJIOKA, Keiichi Kurosowa, Takuto Yonemichi, Koji Fukagata, Tomoaki Okuda, *Keio University*

In recent years, the influence on health by fine aerosol particles such as PM2.5 has been concerned. Especially regarding the particle deposition in a human airway, some previous researches showed that charged particles were deposited to airway surface several times as much as uncharged particles. In other words, when we inhale an aerosol particle, it is deposited on the airway more than expected from its particle size if the particles are charged. However, little knowledge on the electrostatic charging state of atmospheric aerosols has been obtained so far. Therefore, in this study, we measured the charging state of atmospheric aerosols from April 2017 using a parallel electrode plate device utilizing the principle of electric mobility. The results varied depending on the measurement day, and the proportion of charged particles was about 75~88%. By investigating the relationship between the charging state and the weather condition at the time of measurement, it was found that there was a strong positive correlation between the proportion of charged particles and the absolute humidity.

4AP.4

Dynamics of Molecular Ions under the Electrical Field. TOMOYA TAMADATE, Takaaki Orii, Hidenori Higashi, Mikio Kumita, Yoshio Otani, Takafumi Seto, *Kanazawa University*

Highly charged macromolecular ions exhibit various conformations in the gas phase. Intramolecular charge-to-charge interactions induce the transition from the globular structure into the stretched conformation (Larriba and de la Mora, 2012). Such variation of molecular conformation causes complex gas phase dynamics of ions under the electrostatic field. In the present study, the dynamics of multiply-charged molecular clusters were visualized by molecular dynamics (MD) simulation.

The MD simulation was performed by the system consisting of one molecular ion (PEG or tetra-alkyl ammonium ion) with 200 N_2 molecules located in a cubic simulation cell (L=20 nm). The temperature was set at 298 K. In order to simulate the electrical drift of the molecules, the electrical field was applied as $E_x = E_y = E_z = 10{,}000\ \mathrm{V\ cm^{-1}}$.

From the results of visualization by the simulation, the conformation of multiply charged PEG molecules in the gas phase changed from sphere to the non-spherical (string shape) due to the repulsive force between partial charges on the molecule. Such structural transition depends on the number of charges and molecular weight of PEG. In addition, the orientations of the highly charged PEG molecules varied under the electric field. Therefore the transport properties of the highly charged ions were influenced by the molecular structure, charge localization, and orientation.

The electrical mobility of molecular ions was calculated from the change in the position during the specific time interval. Firstly, the MD-calculated mobility of the spherical molecules was validated by the comparison with theoretical values obtained by the Stokes-Einstein's equation. Then, the electrical mobility of the PEG molecules was calculated by the MD simulation with changing molecular weight and the number of charges. It was found that the change in the conformation of the PEG molecules caused a decrease in the calculated mobility, which was also reported in the literature. Thus, the MD simulation is considered to be an effective tool to estimate the electrical mobility of the highly charged macromolecules.

4AP.5

Effects of Dehydration Conditions on Particle Morphology and Activation Ratio of Inorganic Nanoparticles by a HT-DMA- APM / CCNC System.

TA-CHIH HSIAO, Po-Hsiang Huang, *National Central University*

Morphology of aerosol particles may play an important role in pharmaceuticals, powder industry, and atmospheric science. Numerous literature has shown dry particle shape depend on the dehydration condition and crystallization process. Hygroscopic tandem differential mobility analyzers (HT-DMA) are generally used to study the hygroscopic behavior of aerosol particles, however, it cannot provide the information about particle morphology and density. Therefore, in this study, in addition to a HT-DMA system, a hygroscopic coupled tandem DMA and aerosol particle mass analyzer (APM) were integrated and employed. The former size change and latter mass were used to derive the particle effective density and calculated dynamic shape factor which characterize particle shape.

The experimental results indicated that the solvent evaporation and solute diffusion dominated the morphology of the dry particles in dehydration process. In an extreme dry condition, the particle tended to form in irregular shape due to the fast remove of solvent. In contrast, there was more sufficient time for the solute diffusion in slow drying and the particle formed in spherical shape. However, drying and crystallization of aqueous aerosol particle were complicated process. Numerous factors such as materials, solute concentration, and particle size could affect the dry particle morphology. Thus, in order to investigate the dehydration process of aerosol particle, this study combined the diffusion equation and Köhler theory. In addition, quantifying the competitive relationship between solvent evaporation and solute diffusion by the dimensionless parameter: Peclet number and revealing the mechanism of particle formation in different experimental parameters setup. To understand the ability of nanoparticles to activate as cloud condensation nuclei in different drying condition. This study also conducted the HT-DMA-CCNC measurement and showed the activated fraction could be influenced by particle morphology.

4AP.6

Impact of Turbulence Parameters Influences on New Particle Formation Events in August Beijing. HAO WU, Fang Zhang, Zhanqing Li, Peng Yan, Yuying Wang, Xiaoai Jin, Xinxin Fan, *Beijing Normal University*

The Turbulent Kinetic Energy (TKE) affects convection, turbulence and entrainment, which can thus alter nucleation process due to the turbulent mixing that influences local supersaturation of precursor gases during New Particle Formation (NPF). During our experiment conducted in Beijing in August, we noted that the KTE occurs half an hour earlier than the particle burst. A further investigation of these cases suggests that the surface turbulence has a close relationship with the NPF event. A possible explanation is that short-time local supersaturation can trigger the binary nucleation process. Furthermore, we compared the Bowen Ratio (BR) with the growth rate (GR) and the condensation sink(CS), found that they are positively related. The Monin-Obukhov length(L) has a large fluctuation before the nucleation burst. Based on these findings, we proposed a kinetic mechanism of formation from the perspective of thermodynamic, and further explore the TKE and BR together with L as an indicator of NPF, association with other parameters such as Photosynthetically Active Radiation (PAR) or Net Radiation (NR) simultaneously. As aerosols won't affect climate much until they grow to certain size, typically over tens of nm when they can be activated to form cloud droplets, Such particles are referred to as Cloud Condensation Nuclei.

4AP.7

Mathematical Modeling of Aerosol Formation from Binary Vapor Mixtures. Ali Rostami, Sergey Fisenko, SERGEY N. MAXIMOFF, David Kane, Yezdi Pithawalla, Mohamed El-Shall, *Altria Client Services LLC*

Characterizing the aerosol produced by an Electronic Nicotine Delivery System (ENDS) is necessary for regulatory compliance and for designing and optimizing device performance. ENDSs produce condensation aerosol by mixing a high temperature vapor mixture with ambient air, resulting in a vapor mixture at high supersaturation. To characterize the resulting aerosol, it is important to estimate the homogeneous condensation nucleation rate, droplet size distribution, droplet composition as well as vapor-liquid partitioning. In circumstances where the supersaturation is very high and the critical cluster size is smaller than a dimer, the Classical Nucleation Theory (CNT) does not apply.

We addressed this limitation by developing a computational model that uses kinetic theory of gases to calculate nucleation rate and aerosol formation for binary mixtures of propylene glycol (PG) and glycerin (G) vapors. The process involves ternary collision of two vapor molecules of different kinds and any third molecule. The model accounts for non-isothermal growth of clusters with free molecular regime approximation where the cluster size is much smaller than the mean free path of vapor molecules. The latent heat of phase change, that affects the temperature difference between clusters of molecules and gaseous mixture, was accounted for in the model. An ideal liquid mixture solution was assumed for the droplets to account for the vapor-liquid partitioning of each constituent. After 200 ns of free molecular condensation the main mechanism responsible for droplets growth will be coagulation.

Computations were performed for different PG/G mixture ratios, ranging from 0/100 to 100/0 (mole based). Under ideal adiabatic mixing with air, at a vapor temperature of 570 K (close to glycerin boiling temperature), the initial supersaturation of glycerin drops several orders of magnitude. Particle size distribution over time and particle composition were calculated and presented. It was shown that final droplet size distribution is determined by coagulation. The temperatures of droplets and gaseous mixture are the same, due to high heat transfer coefficient at the particle-gas interface. The droplet composition for PG/G mixture strongly depends on the glycerin partial supersaturation in the initial mixture. The mass median diameter of aerosol particles, 1 s after mixing reaches 1-1.5 µm, and shows small dependence on the PG/G ratio and temperature. For all practical purpose, coagulation stops when the number density of micron size droplets decreases to less than about 10^{14} droplets/m^3.

4AP.8

Estimation of Atmospheric Columnar Organic Matter (OM) Mass Concentration from Remote Sensing Measurements.

YING ZHANG, Zhengqiang Li, Yang Lv, Yisong Xie, *Institute of Remote Sensing and Digital Earth, CAS*

Aerosols have adverse effects on human health and air quality, changing Earth's energy balance and lead to climate change. The components of aerosol are important because of the different spectral characteristics. Based on the low hygroscopic and high scattering properties of organic matter (OM) in fine modal atmospheric aerosols, we develop an inversion algorithm using remote sensing to obtain aerosol components including black carbon (BC), organic matter (OM), ammonium nitrate-like (AN), dust-like (DU) components and aerosol water content (AW). In the algorithm, the microphysical characteristics (i.e. volume distribution and complex refractive index) of particulates are preliminarily separated to fine and coarse modes, and then aerosol components are retrieved using bimodal parameters. We execute the algorithm using remote sensing measurements of sun-sky radiometer at AERONET site (Beijing RADI) in a period from October of 2014 to January of 2015. The results show a reasonable distribution of aerosol components and a good fit for spectral feature calculations. The mean OM mass concentration in atmospheric column is account for 14.93% of the total and 56.34% of dry and fine-mode aerosol, being a fairly good correlation (R=0.56) with the in situ observations near the surface layer.

4AP.10

Organic Aerosol Evolution from Wood Combustion Chamber during the Dilution Process. QIJING BIAN, Ezra Levin, Taehyoung Lee, Jeffrey R. Pierce, Sonia Kreidenweis, *Colorado State University*

Previous laboratory and field measurements have documented an increasing oxygenated fraction of organics during aerosol aging and atmospheric oxidation of compounds released in biomass burning plumes. In the laboratory burn experiments carried out as part of the FLAME III study, we diluted smoke stepwise under conditions of minimal oxidation, and observed an increase in the fractional contributions of less oxygenated compounds (C_xH_yO) and a decrease in the fraction of more oxygenated compounds ($C_xH_yO_z$), leading to a slight increase in the O:C ratio in the aerosols as the smoke was diluted. The volatility distributions for C_xH_y, C_xH_yO and $C_xH_yO_z$ were derived from the dilution data, and showed $C_xH_yO_z$ released during biomass burning has similar volatility distribution with C_xH_y but higher volatility than C_xH_yO. In addition, we also found that f60 (the fractional contributions of mass fragments with m/z 60, $C_2H_4O_2^+$, one of the species in $C_xH_yO_z$ family and a marker for biomass burning) decreased, and f44 (the fractional contributions of mass fragments with m/z 44, attributed by both CO_2^+ and $C_2H_4O^+$, and usually a marker of oxidized species) increased, with dilution in some burns. Our studies suggest that apparent trends in f44, aerosol oxidation state and O:C ratio observed in field measurements may not be due solely to oxidation processes, but may also have contributions from physical dilution processes occurring in biomass burning plumes.

4AP.11

Time-dependent Robin Boundary Condition for Convective Diffusion Equations. Panagiotis Neofytou, Marika Pilou, Christos Housiadas, YANNIS DROSSINOS, *European Commission, Joint Research Centre*

Convective diffusion of nanoparticles in bounded flows is an important transport mechanism in many industrial processes. Particle deposition via convective diffusion is of importance to, among others, scrubbers and filters, and aerosol measurement systems. An essential element in the calculation of nanoparticle deposition is the choice of the wall boundary condition. Under steady-state conditions, the wall boundary condition is usually taken to be totally absorbing, namely the particle concentration vanishes at the wall.

Microscopic considerations based on a generalized Fokker-Planck equation for the motion of a particle in a fluid suggest that a properly defined wall boundary condition relates the particle concentration at the wall to its derivative (at the wall). This boundary condition is known as the Robin boundary condition or radiation boundary condition. The associated constants (in the absence of external forces) depend on the particle diffusion coefficient, the particle thermal velocity, and the probability of particle adhesion to the wall (the momentum accommodation coefficient or the sticking fraction). As such, for most aerosol applications at atmospheric pressures and for high particle sticking probabilities the calculated deposition profile or total deposited mass do not depend on whether the Robin or the absorbing boundary is used. In fact, under these conditions the Robin boundary condition reduces to the absorbing boundary condition (i.e., a Dirichlet boundary condition).

The Robin boundary condition is common in systems where a heterogeneous reaction occurs at the wall because it connects the diffusive flux towards the wall to the particle flux that adheres to the wall. The proportionality constant is related to the heterogeneous reaction rate at the wall. Such relevant cases are encountered in, for example, biomedical uses of inhaled particles designed for targeted drug delivery at specific sites of the respiratory system.
We extended the Robin boundary condition to transient situations. Under non steady-state conditions an additional, first order derivative term appears in the time-dependent boundary condition. We investigated the conditions under which this additional time-dependent term influences deposition patterns of nanoparticles in various flows of interest in aerosol and biomedical applications (e.g., in laminar pipe flow).

4AP.12

Comparison of the Particle Growth Rates at Three Background Stations in the Czech Republic. Adéla Holubová Šmejkalová, HELENA PLACHÁ, Bitter Miroslav, Nadežda Zíková, Vladimír Ždímal, *Charles University*

Atmospheric aerosols as ubiquitous particles affect besides human health also climate. One of the key phenomena strongly affecting climate is new particle formation (NPF) and their consequent growth. NPF has been observed in many types of environments and geographical locations (Dall'Osto et al., 2018, Kulmala et al. 2004, Pushpawela et al. 2018, Sitho et al. 2006).

NPF and growth rates are controlled by several factors (concentration of pre-existing aerosols, precursor gases, air masses origin, meteorological conditions, and solar radiation) that are closely related to a sampling site (Jeong et al. 2010 , Nieminen et al. 2012). To explore possible differences in particle growth rates at various locations, measurements of number size distributions of atmospheric aerosol at three background stations in the Czech Republic were carried.

Two stations - Ústí nad Labem (50°39´39"N, 14°2´35"E, 147 m a.s l.) and Lom (50°35´8"N, 13°40´ 24"E, 265 m a.s.l.) are situated in northern, industrial part of the Czech Republic. Ústí nad Labem is urban background station in residential and commercial zone. Lom is rural background station in industrial and natural zone. National atmospheric observatory Košetice (NAOK – 49°34´24"N, 15°4´49"E, 534 m a.s.l.) is located in Czech-Moravian Highland. NAOK is rural background station in agricultural and natural zone.

The number size distributions were measured by aerosol spectrometers SMPS (IfT Tropos) in size range 10 to 800 nm. SMPS data were evaluated from March 1 to August 31, 2017. The growth rate (GR) of the particles freshly formed during the NPF event days was estimated by time evolution of the geometric mean diameter (GMD) of particles smaller than 100 nm. NPF event days were determined by Dal Maso et al. (2005) classification. Condensation sink (CS) was calculated by integration over the aerosol particle size distribution according to Kulmala et al. (2005).

Based on the calculated GR10, CS values and NPF frequencies, the three locations were compared. Results from 24/7 air quality monitoring gives evidence that Ústí nad Labem and Lom are more polluted locations than NAOK. Average PM10 concentrations at Ústí nad Labem and Lom fluctuated around 20 µg•m-3, SO2 ranged from 4 to7 µg•m-3 and NO2 varied between 8 and 19 µg•m-3. Average concentrations at NAOK were 15 µg•m-3, 2 µg•m-3 and 6 µg•m-3, for PM10, SO2 and NO2, respectively.

We observed 52 NPF event days at Lom, 47 NPF event days at NAOK and 43 NPF event days at Ústí nad Labem. GR10 was similar at Ústí nad Labem and Lom stations (median slightly over 3 nm•h-1). At NAOK, median of GR10 was 2.6 nm•h1. On average, CS was higher by a factor of 1.3 at Ústí nad Labem and Lom stations compared to NAOK (median 0.007s-1). Similarities of GR10 and CS between Ústí nad Labem and Lom stations can be caused by a common source, chemical industry, besides other things. In cases when GR was higher than median, pollutant concentrations were slightly higher, especially SO2 concentrations at Lom station.

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 654109 and is supported by Ministry of Education, Youth and Sports of the Czech Republic within project ACTRIS-CZ - LM2015037.

4AP.13

Numerical Study of Nano-Aerosol Generation through Rayleigh Fission of a Charged Viscous Liquid Drop. NEHA GAWANDE, Mohit Singh, Y.S. Mayya, R.M. Thaokar, *Indian Institute of Technology Bombay*

Electro-hydro-dynamic atomization is increasingly used for the production of nanoparticle aerosols. In this technique, a conducting liquid issuing from a needle maintained at a high electric potential with respect to ground, develops a Taylor cone from which highly charged primary droplets are ejected. The charges and the sizes of these droplets, which are generally in the range of several micrometers, depend on the various electro-hydro-dynamic properties of the system. These droplets further disintegrate into smaller droplets by successive Rayleigh fission events. Although the droplets are initially in the sub-Rayleigh limit, they gradually shrink to the radius (a) corresponding to the Rayleigh limit ($a^3=Qc/(64\pi^2\epsilon_0\gamma)$ where, Qc = charge on the droplet, γ =surface tension, ϵ_0=permittivity of free-space) due to evaporation. Although the Rayleigh fission process has been observed experimentally (Duft et al., 2003), the characteristics of the jet formed are still unclear. An understanding of the instability and breakup of such charged droplets from theoretical perspectives is essential for the effective design of the electrohydrodynamic system for the aerosol generation.

Towards this, we model (Gawande et al., 2017) the Rayleigh fission process of a perfectly conducting charged drop of a viscous liquid using a numerical scheme based on boundary element methods. The governing equations involve Laplace equation for the electric potential and Stokes equation for flow field. It is found from the simulations that the drop progressively deforms into a conical shape with pointed ends just prior to break up. As the numerical approach fails to predict charge ejection due to the occurrence of a singularity at this point, the charge loss fraction is estimated by determining how much minimum charge must be removed if the drop is to relax back to a spherical shape. In this manner, the charge loss due to Rayleigh fission (the difference between the original charge and the minimum charge removed) is estimated to be about 39%, which falls within the range of experimental data lying between 20% and 50%. The results on scaling laws, timescales of the process, and the role of various stresses on the dynamics of the drop are also discussed.

Diffraction, Shadows and Scattering in Electrodynamics: A New View. Matthew Berg, CHRISTOPHER SORENSEN, *Kansas State University*

Diffraction is the spreading of waves of any kind. The mechanism of diffraction, however, can be quite different for different types of waves.

We show that for electromagnetic waves such as light the diffracted wave of an object is the Ewald-Oseen extinction wave in the far field. The intensity distribution of this wave yields what is commonly called the diffraction pattern. This is the same Ewald-Oseen extinction wave that extinguished the incident wave in the object and thereafter continued to do so immediately behind the object to create a shadow. The object can be an isolated particle or a screen with a hole; in the former case the Ewald-Oseen extinction wave is radiated from the particle, in the latter case it is radiated from the screen. This point of view explains Babinet's principle. If the object is an isolated, non-absorbing particle, nearly half the scattering cross section is in the Ewald-Oseen extinction wave; if the particle has significant absorption, nearly all the scattering cross section is contained there.

Unlike other common waves, such as sound and water waves, electromagnetic waves do not require a material medium in which to propagate. Thus a material object cannot block electromagnetic waves. Hence, light shadows do not form by blocking the light; light does not bend around the edges of the blocking object.

4AP.15

Physical and Optical Properties of Aerosols over Indo-Gangetic Basin. ASHOK JANGID, Suresh Tiwari, Ranjit Kumar, *DEI, Dayalbagh, Agra*

Aerosols are ubiquitous in nature and play a very important role in radiative forcing, climate change, visibility impairment, reduction in rain intensity and health-related issues. Aerosols have the variable behaviour of absorption and scattering of radiation due to nature of chemical constituents. Hence, estimation of radiative forcing of aerosols is important for which study on physical and chemical properties of aerosols is necessary. A systematic and long-term study on the understanding of properties of aerosols and its radiative forcing has been carried out at Agra over the Indo-Gangetic basin. The measurements of the mass concentration of aerosol (PM10 and PM2.5), black carbon (BC) and Aerosol Optical Depth (AOD) and monitoring of meteorological conditions have been performed. The mean concentration of PM10 (185.8 µg m-3), PM2.5 (94.2 µg m-3), black carbon (8.3 µg m-3) and AOD (0.93) has been determined. The concentration of PM10 and PM2.5 is 2-3 times higher than the NAAQS standard and 7-8 times higher than WHO standard. The high load of aerosol may be due to excessive vehicular emissions and road paved dust. Agra is surrounded by Rajasthan and lots of sand particles released from the grinding of marbles and red stone might be contributing towards a high load of aerosols. Black carbon concentration during night time may be also attributed to the increase in biofuel/biomass burning, especially for cooking as well as for heating purposes. The presence of fine mode particle enhances the radiance scattering and therefore, the aerosol optical depth (AOD) values are high at the shorter wavelength. Aerosol optical depth has been shown relatively strong wavelength dependence of optical depth at shorter wavelengths that generally decreases towards longer wavelengths irrespective of the seasonal change.

4AP.17

Characteristics and Relative Humidity Dependence of the Condensational Growth of Secondary Organic Aerosol Particles in a Continuously Mixed Flow Reactor. YUEMEI HAN, Jinghao Zhai, Chlóe Vercruysse, Yiming Qin, Jianhuai Ye, Scot T. Martin, *Harvard University*

Condensation of low volatility and semivolatile organic gas-phase species is an important atmospheric process for nucleated particles growing up to large sizes that might act as cloud condensation nuclei to impact the climate. The formation and subsequent growth of atmospherically relevant aerosol particles have been investigated extensively using laboratory environmental chambers. However, most of the previous studies are performed under limited relative humidity (RH) or even dry conditions, differing from those in the ambient atmosphere over a range of RH values. The influence of RH on the condensational growth and evolution of secondary organic material (SOM) remains poorly understood. In the current study, SOM was generated from the dark ozonolysis of alpha-pinene in a continuously mixed flow reactor, the Harvard Environmental Chamber, from dry to high RH conditions. The condensational growth of particle population was characterized from their number-size distributions measured in real-time using a scanning mobility particle sizer. The chemical composition of SOM particle was measured continuously with aerosol mass spectrometry. A strong nucleation of SOM particles occurred immediately after turning on the ozone lamp, followed by a series of particle growth events throughout the entire experiments. The chemical composition and oxidation state of SOM particles changed slightly with variable RH, which is possibly due to the influence of RH on the gas-particle partitioning of condensable organic compounds. The condensational growth rate and the time scale of growth will be derived from the evolution of particle number-size distributions for the individual RH values. The potential dependence on RH will be parameterized and incorporated into an analytical equation to optimize the characterization of condensational growth of SOM particle. Results from this study would be helpful to understand the gaps in the condensational growth of aerosol particles in laboratory studies compared to those in the real atmosphere.

4AP.18

Influence of Design Parameters and Operating Conditions on the Aerosol Produced by a Laskin Nozzle. BENOIT SAGOT, Louise Chazalon, Lyes Ait Ali Yahia, *ESTACA*

Oil separators are used in the automotive industry for the separation of oil mist from blow-by gases in internal combustion engines. These so-called “blow-by gases” result from leakages between the combustion chamber and the crankcase. These gases flow through the crankcase, which contains lubricating oil and the resulting oil mist, has to be cleaned up, for pollution control, oil consumption reduction and also to avoid turbo charger oil coking. To compare oil mist separators performances in laboratory, it is necessary to reproduce the engine operating conditions such as temperature and flow rates but also in terms of oil droplets distribution, and we developed such a laboratory bench.

A new generation of SI engine is currently under development, and new trends in engine design are a reduction of the engine size, an increase of the engine temperature, and a reduction of the oil viscosity. The targets are reduction of friction, increase of the overall efficiency, together with a reduction of the pollutant emissions. However, we observed that these changes in the design produced a strong increase of the overall oil mass concentration of blowby gases, which has been multiplied by a factor over 10. At the same time, the mean mass diameter of the aerosol distribution has been strongly reduced. We attribute this modification of the aerosol distribution to the reduction of the oil viscosity, and to higher cylinder pressure. Classical separation systems used in SI engines are based on impactors or cyclones. But to maintain the separation efficiency for the submicronic fraction of oil mists, car manufacturer are now using new systems that include filtration media, with high collection efficiencies and low pressure drop. For filter manufacturers, there is a new challenge: they test these filters on laboratory benches, with gravimetric measurements based on Andersen cascade impactors, and the downstream measurement time is very long (hours), since classical Laskin generators are not capable of producing a high concentration of the submicronic fraction of the aerosol. Therefore, for the submicronic fraction, there is a high uncertainty on the collection efficiency, even for long measurement times that also impose a high stability of the aerosol generation.

The aim of this study is to investigate the capacity of the Laskin nozzle to generate highly loaded oil mist with a low mean mass diameter, with a distribution equivalent to what is currently measured in under development SI engines. The first point is to quantify the impact of operating conditions such as oil temperature and gas flow rate in the Laskin nozzle, on the produced aerosol, in a wider range than what can be achieved with commercial devices such as the Palas PLG 2010.

We observed that for a given Laskin nozzle, the oil temperature has a strong impact of the overall oil concentration, with a limited variation of the mean mass diameter. These results are correlated to the reduction of the oil viscosity. The oil temperature was varied in the range 100°C to 200°C, and we observed a thermal degradation of the oil (SAE 0W30) for temperature higher than 160°C.

The flow rate in the Laskin nozzle has a strong impact on both the overall oil concentration, and on the aerosol distribution. The increase of the flow rate first produces an increase of the overall oil concentration. Then, a dilution effect appears, and we observe a bell shape curve for this oil concentration. However, for the submicronic fraction of the aerosol which is our main concern, the amount of oil droplets produced keeps increasing, which produces a reduction of the mean mass diameter. The last point of this study concerns an investigation of the influence of the geometrical parameters of the nozzle on the produced aerosol: for a fixed gas flow, we tested five nozzles with diameters in the range 0,3 to 1 mm. Based on Andersen cascade impactor gravimetric testing, the influence of the gas nozzle diameter was characterized.

With this experimental study, we were able to produce an oil mist distribution close to what is measured on under development SI engines. We got a better understanding of the way a Laskin nozzle works, which will be helpful for further development of filtration systems.

4AP.19

Light Scattering Analysis of Irregularly Shaped Dust Particles: A Study Using 3-Dimensional Reconstructions from Focused Ion-Beam (FIB) Tomography and Q-Space Analysis. DIANA ORTIZ-MONTALVO, Joseph Conny, *National Institute of Standards and Technology*

We study the scattering properties of irregularly shaped ambient dust particles. The way in which they scatter and absorb light has implications for aerosol optical remote sensing and aerosol radiative forcing applications. However, understanding light scattering and absorption by non-spherical particles can be very challenging. We used focused ion-beam scanning electron microscopy and energy-dispersive x-ray spectroscopy (FIB-SEM-EDS) to reconstruct three-dimensional (3-D) configurations of dust particles collected from urban and Asian sources. The 3-D reconstructions were then used in a discrete dipole approximation method (DDA) to determine their scattering properties for a range of shapes, sizes, and refractive indices. Scattering properties where obtained using actual shapes of the particles, as well as, (theoretical) equivalently-sized geometrical shapes like spheres, cubes, and tetrahedrons. We use Q-space analysis to interpret the angular distribution of the scattered light obtained for each particle. Q-space analysis has been recently used to distinguish scattering by particles of different shapes, and it involves plotting the scattered intensity versus the scattering wave vector (q or qR) on a log-log scale, where $q = 2k\sin(\theta/2)$, $k = 2\pi/\lambda$, and R = particle effective radius. Results from a limited number of particles show that when Q-space analysis is applied to 3D models of irregularly shaped particles (from FIB tomography), common patterns appear that agree with previous Q-space studies done on ice crystals and other irregularly shaped particles. More specifically, we found similar Q-space regimes including a forward scattering regime of constant intensity when $qR < 1$, followed by the Guinier regime when $qR \approx 1$, which is then followed by a complex power law regime with a -3 slope regime, a transition regime, and then a -4 slope regime. Currently, Q-space comparisons between actual and geometric shapes are underway with the objective of determining which geometric shape best represents the angular distribution and magnitude of the scattered light. Current work also focuses on the effects of the imaginary part of the refractive index on the light scattering of our dust particles. Preliminary data show that agreement between models for the geometric shapes and the actual shapes of particles varies substantially with particle size. Better agreements were observed for smaller particle sizes. Overall, shape and size cause more variability in the data than differences in chemical composition.

4AP.20

Physical Characterization of Tire Wear Particles Generated by Tire Simulator According to the Tread Wear Rate of Tires. SEOKHWAN LEE, Gibaek Kim, *Korea Institute of Machinery and Materials*

Vehicles emit particulate matter (PM) through their exhaust and non-exhaust sources. Exhaust PM can be generated by incomplete fuel combustion and lubricant volatilization. Non-exhaust PM can be emitted through tire, brake, and road wear processes and re-suspension of road dust. Due to the increasingly stringent regulations of the vehicle exhaust emissions, the relative contribution of non-exhaust PM become more significant. Among the non-exhaust PM, tire wear particles (TWPs) having relatively high uncertainty in physical properties have been less studied.

In this study, the tire simulator was operated in a closed control chamber (L: 3.5 m x W: 2.4 m x H: 2.2 m) to enable the detection of TWPs, thus excluding contamination particles originated from the other sources. TWPs were introduced into the sampling ports connected with several measurement instruments. DustTrack DRX, aerodynamic particle sizer (APS), fast mobility particle sizer (FMPS) spectrometer, condensation particle counter (CPC), and optical particle counter (OPC) were used to measure the various physical properties of TWPs such as number concentrations, number size distributions, mass size distributions, and mass concentrations (PM2.5 and PM10). The results suggest that the physical properties of TWPs can be affected by the tread wear rate of tires.

4AP.21

Aerosol Self-Cleansing by Dry Deposition in the Amazon Dry Season. FLORIAN DITAS, Christopher Pöhlker, Henrique Barbosa, Joel Brito, Samara Carbone, Xuguang Chi, Bruna A. Holanda, Isabella Hrabe de Angelis, Tobias Könemann, Jing Ming, Mira L. Pöhlker, Maria Prass, Daniel Moran-Zuloaga, Marta Sá, Jorge Saturno, Hang Su, Jian Wang, David Walter, Stefan Wolff, Alessandro Araujo, Paulo Artaxo, Ulrich Pöschl, Meinrat O. Andreae, *Max Planck Institute for Chemistry*

The Amazon rainforest is one of the few continental places where the atmospheric composition is episodically close to a pristine state. Local, regional and global anthropogenic pollution transported into the Amazon basin is chemically transformed and effectively deposited by wet and dry deposition.

This work focuses on observations in the central Amazon region – at the *Amazon Tall Tower Observatory* (ATTO). The ATTO site is equipped to measure aerosol microphysical, optical, chemical and morphological properties at two different measurement towers, which allows observations inside (5 m), close to (60 m) and well above (325 m) the forest canopy.

Vertically resolved meteorology and aerosol properties suggest a stable stratification during night resulting in a pronounced layering of aerosol particles. Frequent advection of pollution plumes during night leads to a massive increase of the aerosol burden above the canopy which is easily able to double the total number concentration. After sunrise, convection enables mixing and lofted aerosol layers are mixed downwards. Consequently, the particle concentration increases sharply close to and below the canopy. As soon as a well-mixed boundary layer is developed, particle properties are similar at all three measurement heights. In the course of the day, the total particle concentration features a pronounced decay which is to a certain degree related to the forest‘s self-cleansing capacity.

Acknowledgements. We thank the Max Planck Society and the Instituto Nacional de Pesquisas da Amazonia for continuous support. We acknowledge the support by the German Federal Ministry of Education and Research (BMBF), the Brazilian Ministério da Ciência, Tecnologia e Inovação (MCTI/ FINEP) and the Amazon state University (UEA), FAPEAM, LBA/INPA and SDS/ CEUC/RDS Uatumã.

4AP.22

Aerosol Optical Property Measurements of European Background Aerosol under Clean and Polluted Conditions.

SEBASTIAN DÜSING, Birgit Wehner, Albert Ansmann, Holger Baars, Ralf Käthner, Nan Ma, Thomas Müller, Patric Seifert, Holger Siebert, Gerald Spindler, Alfred Wiedensohler, Nicolas Bukowiecki, Joel Corbin, Martin Gysel, *Leibniz-Institute for Tropospheric Research*

Observations of the vertical distribution of aerosol are quite important since they allow to describe the radiative transport in the atmosphere. For this, remote sensing and airborne in-situ measurements are potential approaches to study the vertical aerosol distribution. But, both approaches underlie limitations and assumptions. Inter-comparison studies are therefore needed to a) compare the results of these approaches and b) to improve remote sensing algorithms and provide recommendations for vertical in situ measurements. Two campaigns were conducted and the results of these unique data-set for European background aerosol will be presented in this contribution.

Both campaigns took place in the vicinity of the rural ACTRIS (Aerosol, Clouds, and Trace gases Research InfraStructure Network) super-site at Melpitz (51.5° N, 12.9° E and 90 m above sea level).

In the first campaign (June 2015) 11 flights were conducted with a helicopter-borne payload up to a height of 2.3 km. This payload determined a) the ambient RH, T and b) the aerosol particle number size distribution (PNSD) within a particle diameter-range from 8 nm to 2.8 µm. Each flight contained horizontal flight legs of at least 10 min to determine statistically significant mean PNSD measurements. Three different instruments recorded the aerosol optical properties: particle light absorption (σ_{abs}) was determined by a small sized Aethalometer (AE51) at 880 nm wavelength whereas the Single Channel Tri-Colour Absorption Photometer (STAP) measured σabs at 450, 525, and 624 nm, while scattering (σ_{sca}) and extinction coefficient (σ_{ext}) were recorded with the Cavity Attenuation Phase Shift monitor (CAPSssa) at 630 nm wavelength.

In the second campaign (February/ March 2017) a box deployed on a tethered balloon included instruments determining σabs during 5 launches (AE51, STAP). The PNSD has also been detected within an optical particle diameter-range of 300 nm to 10 µm. All in situ measurements were conducted under dry conditions below 40% RH.

In both campaigns, the in situ measurements were complemented by a continuously running ground-based 3+2 multiwavelength polarization Raman lidar system PollyXT measuring profiles of the aerosol particle light backscatter coefficient (σ_{bsc}). Also we derived profiles of σext. Furthermore, an almucantar sun-photometer was measuring the aerosol optical thickness at different wavelengths.

These measurements were completed by measurements of the chemical aerosol composition as well as by measurements of the aerosol optical properties on ground. On the basis of the chemical composition measurements we derived the complex refractive index and the hygroscopicity of the aerosol particles.

Assuming that the chemical composition on ground is applicable for higher atmospheric altitudes, we first converted the in situ measured PNSD to its ambient state PNSD which has been used furthermore to calculate ambient state aerosol optical properties with a Mie theory based model.

Our measurements show that ground-based measurements are representative for the well-mixed planetary boundary layer. Furthermore, the in situ dry state modelled σ_{sca} and σ_{ext} showed good agreements with the airborne in situ measured equivalents. But especially the comparisons with filter-based absorption (σ_{abs}) instruments (STAP, AE51) and our Mie-calculations showed deviations which requires further research. Comparing the ambient state optical properties (model and in situ) with the measurements of the lidar, we detected cases were the model is in agreement (within measurement uncertainties) with the lidar observations. But we also observed also cases were the model calculated significantly lower σ_{ext} and values than observed by the lidar.

Not all flights/lunches are investigated yet, but conclusions and findings of the observations will be presented in this conference contribution.

4AP.24

Charge Size Distribution of Aerosol Nanoparticles Generated by Electrical Heating: Measurements and Theory.

MARIAM , Manish Joshi, Arshad Khan, B.K. Sapra, *Bhabha Atomic Research Centre, Mumbai*

Aerosol particles (natural and/or anthropogenic) are electrically charged, either because of the underlying formation mechanism or by their interactions with surrounding ionic environment. Knowledge of electrical behaviour of charged particles is applicable in several fields like drug delivery, electrostatic precipitators, residence time of aerosols etc. (Kwok et al., 2006; Pettersson et al., 2010). Type of aerosol particles as well as their generation method have a significant effect on the magnitude of the particle charge. This work focuses on estimation of charge size distribution (measurements and theoretical interpretation) of aerosols generated by electrical heating of nichrome wire using ELPI (Electrical Low Pressure Impactor). A laboratory made hot wire generator was used for generation of nanoparticle aerosols for this context (Khan et al. 2014). For steady conditions, charge per particle was found to be increasing from 0.009 to 1.305 for the size range of 9 to 230 nm (integral number concentration > 10^7 per cm^3). Depending on temperature, thermionic emission and surface ionization are responsible mechanisms, which operate when a metal is electrically heated. For the temperature under glowing conditions, surface ionization is dominant phenomenon and thermionic emission (threshold at much high temperature) is improbable. Theoretical comparisons of current density and polarity at varying temperature were made with experimental findings.

Optical Properties and Chemical Constituents of Ambient Fine Particles in an Urban Environment of Korea. JONGBAE HEO, Seungpyo Cheong, Hwajin Kim, *Seoul National University*

Aerosol optical properties, chemical constituents, and sources of ambient fine particles were measured in Seoul, Korea, from May to November 2016. Light scattering (σscat) and absorption (σabs) coefficients were measured with a photoacustic extinctiometer (PAX) and a multiangle absorption photometer (MAAP), respectively. Chemical components of ambient fine particles were observed using a HR-ToF-AMS and their sources were identified using a positive matrix factorization model. During the study period, average mass concentration of fine particles, organic matter (OM), black carbon (BC), SO42-, NO3-, NH4+, and Cl- were 27.4 (±16.9) µg m-3, 13.0 (±8.3) µg m-3, 1.7 (±1.0) µg m-3, 5.0 (±3.6) µg m-3, 4.7 (±4.9) µg m-3, 2.9 (±2.3) µg m-3, and 0.3 (±0.5) µg m-3, respectively, and OM was a major component of fine particles. The observed σscat and σabs were 131.0 (±94.0) M m-1 and 13.6 (±8.2) M m-1, respectively. Both of the scattering and absorption coefficients showed unique diunal patterns with high peaks during the morning and evening rush hours due to the peak emissions of vehicles and the unfavorable meteorological conditions for dispersion of the vehicle emissions. The average of single scattering albedo calculated was 0.9 (±0.1), representing that fine particles in the study area contain relatively high fraction of scattering chemical components. The average mass scattering efficiency of fine particles was 4.70 m2 g-1 and exhibited higher values in spring and lower values in fall, showing a similar trend to mass of fine particles. This seasonal trend is influenced by the variations on chemical constituents of fine particles. Multiple linear regressions were performed to investigate associations of chemical components of fine particles with extinction coefficient (bext). Results showed that OM contributed the most to bext, accounting for 51.3%, followed by (NH4)2SO4, NH4NO3, and BC, 20.4%, 17.7%, and 9.7%, respectively. The PMF model identified four factors contributing to the OM, including low-volatile oxidized organic aerosol (LV-OOA), semi-volatile oxidized organic aerosol (SV-OOA), cooking influced organic aerosol (COA), and hydrocarbon like organic aerosol (HOA). Among the identified four factors, secondary organic aerosol factors (i.e. LV-OOA, SV-OOA) were the dominant contributors to bext. Therefore, reducing emissions of gaseous precursors corresponding to secondary aerosol formation may be important to improve both of air quality and visibility in Seoul.

4AP.26

Coagulation of Polydisperse Primary Particles from Free Molecular to Transition Regime. Georgios Kelesidis, EIRINI GOUDELI, *ETH Zürich*

Agglomeration of nanoparticles is encountered in both atmospheric and industrial processes as in volcanic plumes and aerosol manufacture of carbon black or fumed silica. Coagulation of polydisperse primary particles (PPs) in the transition regime is the dominant agglomerate growth mechanism in the low-temperature region of flame reactors and high-pressure environments of combustion engines. Even though the dynamics of coagulating spherical particles, such as self-preserving size distribution (SPSD) and coagulation rate are reasonably well-understood, there is significant uncertainty for fractal-like agglomerates. For the latter, coagulation rates have been proposed, their mobility and SPSDs have been determined. All these have been confined to agglomerates with monodisperse primary particles (PPs). Realistic agglomerates, however, consist of polydisperse PPs.

Here coagulation of nanoparticles of varying PP polydispersity (σg,PP = 1 – 3) in the absence of coalescence, sintering or surface growth is investigated by a discrete element method (DEM) (Goudeli et al., 2015) from the free molecular (Goudeli et al., 2016) to transition regime. The effect of PP polydispersity on agglomerate size (radius of gyration, mobility radius and volume-equivalent radius), morphology (fractal dimension, Df, mass mobility exponent, Dfm, and their prefactors) as well as on the attainment of the well-known asymptotic fractal-like structure (Df = 1.91 and Dfm= 2.15) and SPSD is investigated. Increasing the polydispersity of the constituent PPs from σg,PP = 1 to 3 does not affect but only delays the attainment of the asymptotic Df, Dfm and SPSD of the resulting agglomerates. Furthermore, the effect of PP polydispersity on agglomerate dynamics (coagulation rate and polydispersity) is elucidated quantitatively.

Such characteristics affect the environmental impact of agglomerates (climate forcing or visibility impairment by soot) or performance of gas sensors and catalysts.

4AP.27

Single Scattering Albedo of Homogeneous, Spherical Particles in the Transition Region. HANS MOOSMULLER, Christopher Sorensen, *Desert Research Institute*

The aerosol single scattering albedo (SSA) is the dominant intensive particle parameter determining the aerosols radiative forcing in the earth's atmosphere [1-3]. We use Mie theory to examine the behavior of SSA as a function of size parameter x and complex refractive index m for homogeneous spherical particles. Previously, we investigated the limiting cases of the small particle limit ($x << 1$) and the large particle limit ($x >> 1$), where SSA is proportional to x^3 and independent of the size parameter x, respectively [4]. In between these cases lies the transition (or peak) region, where SSA transitions from the small to the large particle regime and, for sufficiently small imaginary parts of the refractive index, shows one or more peaks.

Here, we investigate the behavior of SSA in the transition region including conditions on the complex refractive index for peak formation, peak location, and general properties of SSA as function of size parameter.

Fine Particle Formation in Corona Discharge. VALERY ZAGAYNOV, *National Research Nuclear University MEPhI*

The corona discharge is a gas discharge where geometry confines the gas ionizing process to high field ionization region around active electrode. The corona discharge can be used as a source of positive or negative charges based on the polarity of active electrode (Goldman et.al., 1985). It ought to be taken into account that some plasma is formed across the ionizing region causing ions and electrons colliding onto metal electrodes' surfaces. The energy of charged particles is sufficiently high capable of ionizing the gas molecules resulting from collision. Their energy could be at the level of tens of electron-volts corresponding to tens thousands degrees. It could be supposed that these impacts of electrons onto surfaces could cause some electrode erosion resulting from charged particles and electrons knocking atoms and molecules out of electrode's surface. Then, these displaced atoms and molecules turn into vapor molecules and contribute to the surrounding gas phase. Upon moving away from the ionizing region, the temperature of such vapor molecules rapidly decreases and, any unavoidable collision between each other could potentially move them to the bond states, subject to their ability to release excessive kinetic energy. Thus, fine particles composed of electrode material could be formed (Smirnov, 1999). To investigate this process the experimental set up has been constructed. The set up consists of silver particle generator and diffusion aerosol spectrometer (DAS) capable of measuring concentration and size distribution of produced silver particles. The particle generator consisted of thin silver needle (active electrode) and ring silver electrode. Particles produced in the active electrode region were measured by the DAS at one minute interval providing information about particle size distribution and concentration. Typical size distribution of silver particles produced by the above generator is shown in Figure 1. As is seen from this graph some part of generated particles is not presented in the figure, as it is laying beyond the bottom detection limit of DAS, which is blind for particles smaller than 3 nm. Analyzing the obtained experimental data enabled to estimate an amount of silver atoms (which took part in particle formation) generated by one electron impacting onto the active electrode surface (generation efficiency). To achieve this goal, the electric current of corona discharge, total particle concentration and particle size distribution were accurately measured and the results were used in calculations. Dividing measured electric current by electron charge the electron flow on electrode surface was calculated. Then number of silver atoms which took part in particle formation was estimated by measured particle size distribution and its concentration. On the ground of these estimations it was obtained that efficiency of particle generation is between 10-3 – 10-2. At the same time it has to be taken into account that this is low boundary estimation, because part of particles (most fine) was not recorded due to their location beyond the DAS detection limit. Size distribution of the particles, formatted in corona discharge.

The proposed approach to model nanoparticle generation in corona discharge by the vapor of silver or other metals is supposed to consider coagulation equation for corresponding conditions. This method is promoted by the fact that the vapor transition from hot ionizing region to the region with room conditions is very abrupt, and any collisions between particles could result in bond state. At the same time, this method of particle generation can be useful if very fine particles with narrow size distribution are required.

Temporal Variation of Particles Suspended (TSP, PM10 and PM2.5) and Composition Chemistry of PM10 in San Francisco de Campeche, México. ALBERTO ANTONIO ESPINOSA GUZMÁN, Javier Reyes Trujeque, Javier Miranda, Juan Carlos Pineda SantaMaría, Ana Luisa Alarcón Jímenez, María del Carmen Torres Barrera, Rodolfo Sosa Echevería, *Autonomus University of Campeche*

Air pollution is a global problem that affects both natural environment and human health. Currently, this issue is specially studied due to the higher demand on cleaner environment with low air pollution levels at urban areas, where a better life quality is desirable. In Mexico, studies on atmospheric particles and their effects on air quality and environmental impact, are widely developed in densely populated urban sites. That is the case of metropolitan areas such as Mexico City, Guadalajara, and Monterrey. Moreover, in Mexico smaller cities, such as San Francisco de Campeche (SFC), there is lack of air quality studies, including those related with atmospheric particles. SFC is located on the West coast of the Yucatan Peninsula in the state of Campeche, México.

SFC is bordering by the Gulf of Mexico. It is in the middle of a small valley, limited N, E by small hills. At the W, the Bay of Campeche delimits its coastal area. Some of those hills are subjected to continuous erosion episodes, building of residential developments, or are used to extract materials for construction. These very aggressive activities affect the land, causing dust storms, especially during the dry season. The last one increases local levels of atmospheric particles. During the spring, the City is regularly affected by the traditional farmlands burning produced at the region in order to prepare crops. Also, there appear numerous natural forest fires during dry periods, something that potentially could increase the content of pollutants in the atmosphere. In the last decade SFC increased its population by 17.3% (nowadays around 280,000 inhabitants). Also, the increase in the number of cars rinse the City with one of the most higher number of vehicles per capita in the country. The devices was installed on the roof of the “SEMARNTACAM”, it is located (19.82 N, -90.53 W), at the historic center of the city. The area is characterized by an intense economical and official activities. In this area, important traffic jams can be observed in streets surrounding the buildings along the day.

Elemental analysis for three fractions (TSP, PM_{10} and $PM_{2.5}$) was determined by using X-Ray Fluorescence (XRF). Samples were collected on 8 "x10" quartz fiber filters (Whatman). High volume samplers (Tisch Environment) were used, according to the Official Mexican Standard NOM-035-SEMARNAT-1993. An ion analysis was also carried out for the PM_{10} fraction, using the Ion Chromatography (IC) technique. The sampling period was from November 1st 2014 to October 30th 2015, each three days during 24 hour. Sampling initiated at 8:00 am.

XRF indicated the presence of Al, Si, P, S, Cl, K, Ca, Ti, Cr, Mn, Fe, Cu, Zn and Sr predominant elements. Cluster analysis (AC) determined associations between: K and S; due to smoke emissions probably from the burning of crop fields; Cr, Mn, Cu, (industrial emissions); Ca, Ti and Fe (raising dust). Ionic analysis determined the species: Na^+, K^+, Mg^{2+}, Ca^+ 2, Cl^-, NO^{-3}, $SO4^{-2}$, $HCO3^-$ and high concentrations were of $SO4^{-2}$, Cl^- , Na^+, in dry season for this study. Principal Component Analysis (PCA) applied to ion concentration in PM10 indicating that the contribution the Na^+, Cl^- and Mg^{2+} is due for marine aerosol, Ca^{2+} due crustal origin and NO^-_3, SO_4^{-2} suggests vehicular emissions. Also back-trajectories models showed that biomass burning at farming areas affects the concentration of TSP and PM10 during the dry season.

4CA.1

Sources of PM2.5 Carbonaceous Aerosol in Riyadh, Saudi Arabia. QIJING BIAN, Badr Alharbi, Mohammed M. Shareef, Tahir Husain, Mohammad J. Pasha, Samuel Atwood, Sonia Kreidenweis, *Colorado State University*

Knowledge of the sources of carbonaceous aerosol affecting air quality in Riyadh, Saudi Arabia is limited, but needed for the development of pollution control strategies. We conducted sampling of PM2.5 from April to September, 2012 at various sites in the city, and used a thermo-optical semi-continuous method to quantify the organic carbon (OC) and elemental carbon (EC) concentrations. The average OC and EC concentrations were 4.7 ± 4.4 and 2.1 ± 2.5 µg m-3, respectively, during this period. Both OC and EC concentrations had strong diurnal variations, with peaks at 6-8 am and 20-22 pm, attributed to the combined effect of increased vehicle emissions during rush hour and the shallow boundary layer in the early morning and at night. This finding suggested a significant influence of local vehicular emissions on OC and EC. The OC/EC ratio in primary emissions was estimated to be 1.01, close to documented values for diesel emissions. Estimated primary (POC) and secondary (SOC) organic carbon concentrations were comparable, with average concentrations of 2.0 ± 2.4 and 2.8 ± 3.4 µg m-3, respectively.

We also collected 24 hour samples of PM10 onto quartz microfiber filters and analyzed these for an array of metals by ICP-OES. Total OC was correlated with Ca (R2 of 0.63), suggesting that OC precursors and Ca may have similar sources, and the possibility that they underwent similar atmospheric processing. In addition to a ubiquitous dust source, Ca is emitted during desalting processes in the numerous refineries in the region and from cement kilns, suggesting these sources may also contribute to observed OC concentrations in Riyadh. Concentration weighted trajectory (CWT) analysis showed that high OC and EC concentrations were associated with air masses arriving from the Persian Gulf and the region around Baghdad, locations with high densities of oil fields and refineries as well as a large Saudi Arabian cement plant. We further applied positive matrix factorization to the aligned data set of EC, OC and metal concentrations (Al, Ca, Cu, Fe, K, Mg, Mn, Na, Ni, Pb and V). Three factors were derived, and were proposed to be associated with oil combustion, industrial emissions (Pb-based), and a combined source from oil fields, cement production, and local vehicular emissions. The dominant OC and EC source was the combined source, contributing 3.9 µg m-3 (80%) to observed OC and 1.9 µg m-3 (92%) to observed EC.

4CA.2

Hydroxyl and Nitrate Radical Aging of Organic Emissions from Wildfires. SHANTANU JATHAR, Ali Akherati, Shiva Tarun, Liam Lewane, Abril Galang, Timothy Onasch, Scott Herndon, Joseph Roscioli, Tara Yacovitch, Edward Fortner, Philip Croteau, Wen Xu, Conner Daube, Berk Knighton, Benjamin Werden, Ezra Wood, Christopher Lim, David Hagan, Christopher Cappa, Jesse Kroll, Daniel S. Tkacik, Christopher Hennigan, Allen Robinson, *Colorado State University*

Wildfires are the largest combustion-related source of organic emissions to the atmosphere; these include direct emissions of primary organic aerosol (POA) and semi-volatile, intermediate-volatility, and volatile organic compounds (SVOCs, IVOCs, and VOCs). However, there are large uncertainties surrounding the evolution of these organic emissions as they are physically and chemically transformed in the atmosphere. To understand these transformations, we performed sixteen experiments using an environmental chamber to simulate day- and night-time chemistry of wildfire emissions from 6 different fuels at the Fire Laboratory in Missoula, MT.

Across the test matrix, the experiments simulated 0.5 to 9 hours of equivalent day-time aging (with the hydroxyl radical and ozone) or several hours of night-time aging (with the nitrate radical). Day-time aging resulted in an average organic aerosol (OA) mass enhancement of 72% although the full range of OA mass enhancements varied between ~0% and 400%. The distribution of OA mass enhancements was consistent with chamber and flow reactor experiments performed at the Fire Laboratory in 2010 and 2012 but similar to previous studies offered no evidence to link the OA mass enhancement to fuel type, burn conditions, or oxidant exposure. The chamber OA mass enhancements were nearly half of those observed with flow reactor experiments performed in conjunction with this study and the differences could be explained by significant differences in oxidant exposure (median age of 6.1 hours for the chamber versus 3.8 days for the flow reactor). Night-time aging resulted in an average OA mass enhancement of 20%, which was lower than that observed with day-time aging. We found strong evidence for production of organic nitrates during the night-time experiments where they accounted for ~10% of the total OA emitted and formed by the end of the experiment. Both day- and night-time aging resulted in only modest changes in the OA composition measured by the aerosol mass spectrometer. The median fraction of the OA mass measured at a mass-to-charge ratio of 44 and 60 changed by +65% and -25% respectively and the median oxygen-to-carbon ratio increased by 25%. The flow reactor experiments witnessed much larger changes in the OA composition (e.g., median oxygen-to-carbon ratio more than doubled), which again could be attributed to substantial differences in oxidant exposure.

Ongoing work is focussed on integrating chamber and flow reactor wildfire experiments from 2010, 2012, and 2016 (~130 individual experiments) to examine the relationship between OA mass enhancement ratios, modified combustion efficiency, initial aerosol concentrations and composition, aerosol size, oxidant exposure, VOC:NOx ratios, and emissions and speciation of SOA precursors.

4CA.3

Trend of Elemental and Organic Carbon (EC/OC) Concentrations at the National Atmospheric Observatory Košetice (Czech Republic) in 2009-2016. MILAN VANA, Adéla Holubová Šmejkalová, *Czech Hydrometeorological Institute*

Carbonaceous aerosol particles in the atmosphere are formed mainly of elemental carbon and organic compounds (Seinfeld, Pandis 2006). Elemental (EC) and organic carbon (OC) are the products of imperfect combustion of organic materials (coal, oil, petrol, wood and biomass); sources of OC also include the resuspension of dust, which is related to transport, and biogenic particles. While EC is emitted into the atmosphere only directly, OC can be formed by the reactions of gaseous organic precursors. The large number of toxicological studies collected in the WHO document of 2012 are related to the negative effects of carbonaceous aerosols on human health. Regular EC/OC measurement has been implementing at the National Atmospheric Observatory Košetice (NAOK) since 2009 within the framework of EU-projects EUSAAR (European Supersites for Atmospheric Aerosol Research) and later ACTRIS (Aerosols, Clouds, and Trace gases Research Infrastructure Network) and ACTRIS-2. Sampling frequency is every 6th day on 2 quartz-fibre filters. The samples are analyzed using EC-OC Sunset Lab Dual Analyzer. In 2013, a parallel measurement using a field semi-online OC/EC analyzer from Sunset Instrument started. Both instruments sampled an aerosol fraction PM2.5 and denuders were used to remove volatile organic compounds. Automatic optical corrections (based on a laser transmission monitoring) for charring were made during each thermal-optical analysis. The presented trend study is based on manual data, the data from the analyzer were used only for completing the data series when the manual data is missing. Kosetice Observatory, operated by the Czech Hydrometeorological Institute (CHMI), was established in 1988. The observatory is located in free area outside of settlement (49°35´ N, 15°05´E, 534 m above sea level) and represents the Czech Republic in several international long-term monitoring programmes (EMEP, GAW). Detailed information is available at (Vana et al., 2013).The used statistical method for trend analysis in this study is based on the nonparametric Mann-Kendall test for trend and the nonparametric Sen's method for the magnitude of the trend. The EC emissions in the Czech Republic display continuously decreasing trend from 4,8 (kt) in 2009 to 3,2 kt in 2015. This tendency is reflected in the statistically significant downward trend of EC concentrations at NAOK from 0,6 µg.m-3 in 2009 to 0,3 µg.m-3 in 2016. Slightly decreasing trend was found both in cold (October-March) and warm (April-September) period. The difference between the seasons in not visible. OC concentrations shows decreasing tendency, which is not statistically significant. In the period 2009-2013 the mean annual concentrations stagnated round 3,5 µg.m-3 and then dropped under 3 µg.m-3. The similar tendency is visible also in the cold period. On the other hand, in the warm period, no trend was found. The mean annual ratio of EC on total carbon (TC) was 13%. No visible tendency was found during the period under review. In the warm period, the ratio was lower (11%) with decreasing tendency. On contrary, significant upward trend of the ratio was found in the cold period (mean annual ratio 15%).

The research leading to these results has received funding from the project for support of national research infrastructure ACTRIS – participation of the Czech Republic (ACTRIS-CZ - LM2015037) – Ministry of Education, Youth and Sports of the Czech Republic.

Roadside Measurements of Black Carbon, PM2.5, Particle Number and NOx Vehicle Emission Factors in Brazil.

PATRICIA KRECL, Admir Créso Targino, Thiago Landi, Matthias Ketzel, *Federal University of Technology*

The road transportation sector contributes largely to air pollution in urban areas, and accurate knowledge of vehicle emission factors (EF) is crucial to prepare reliable emission inventories which, in turn, are strategic tools for air quality management. Curbside and rooftop concentrations of several traffic-related species were measured within a busy street canyon in Londrina (Brazil) and EF for NOx, black carbon (BC), fine particles ($PM_{2.5}$) and particle number (N) were calculated based on these measurements and inverse modeling using the Operational Street Pollution Model (OSPM). We highlight the importance of this work in quantifying the effects of possible off-cycle BC, $PM_{2.5}$, NOx and N emissions in urban areas by measuring emissions in real driving conditions in a continent-sized country where there is a lack of EF studies. On average, one heavy-duty vehicle (HDV) emitted more pollutants than one light-duty vehicle (LDV) with EF_{HDV}/EF_{LDV} ratios of 27, 12, 10 and 4 for BC, NOx, $PM_{2.5}$ and N, respectively. Our results are consistent with literature values reported by other studies conducted also under real-world driving conditions in Brazil (São Paulo city). As far as we know, we report the first EFN ever measured in Brazil and when compared to other works carried out in street canyons in Europe, they were similar for the HDV fleet but much higher for the LDV fleet. Our EF are much higher than laboratory measurements conducted in Brazil and Europe, especially for particles. This finding suggests that the EF derived from laboratory tests should be revised for all vehicle categories in Brazil, since they are used to compile official national inventories for the road transportation sector and also to assess their associated health and climate (in the case of BC) impacts. Finally, Brazilian regulators should incorporate certification procedures that more closely resemble real-world conditions. For example, adopting certification tests in laboratory that consider cold-start and low-speed driving and also real drive emission (RDE) testing already in place in the European Union. There is also a need of quantifying the non-exhaust EF for particulate matter and determine mileage deterioration for all pollutants and vehicle categories, which are missing in all official inventory calculations.

4CA.5

Sources of Brown Carbon in Urban Environments: Importance of Vehicular Emissions. NETHMI KASTHURIARACHCHI, Max Adam, Yue Liang, Dong Zhang, Alex Lee, *National University of Singapore*

Carbonaceous aerosols are known to affect the global climate through direct absorption and scattering of solar radiation. While black carbon (BC) is the most efficient light absorbing aerosol, brown carbon (BrC) has been found to efficiently absorb radiation in the near UV and visible wavelengths. Although biomass burning has been extensively studied as a primary source of BrC, there is increasing laboratory evidence that incomplete fossil fuel combustion, such as vehicular emissions, can be a potential source of BrC in urban environments with minimal influence from biomass burning.

In this study, a seven-wavelength Aethalometer (AE33, Magee Scientific), which gives loading factor-corrected absorbance measurements at 370nm, 440nm, 520nm, 590nm, 660nm, 880nm and 950nm, was deployed to measure ambient BC and BrC in Singapore. A co-located soot-particle aerosol mass spectrometer (SP-AMS, Aerodyne Research) was used to measure non-refractory chemical composition of ambient particles. No biomass burning episodes due to transboundary smoke were reported during the month-long sampling period. The mean absorption Ångström exponent (AE) of ambient particles was 1.06 ± 0.05, further indicating the absence of biomass burning influence (i.e., AAE > 2 for biomass burning smoke). Comparison of ambient and thermodenuded (at 200^{o}C) particles confirms the presence of BrC in ambient particles. Assuming AAE of ambient pure BC is equal to 1, the light absorption properties of ambient BrC were quantified. The mean AAE of BrC was estimated to be in the range of 3 to 4, which is comparable to the values measured in urban environments with strong influence from fossil fuel combustion.

Positive matrix factorization (PMF) of organic fragments measured by SP-AMS identified four major types of organic aerosols, including hydrocarbon-like organic aerosols (HOA), cooking-related organic aerosols (COA) and less and more oxidised oxygenated organic aerosols (LO-OOA and MO-OOA). Out of the four types of organic aerosols, HOA showed the strongest correlation ($r^2 = 0.6$-0.7) with the BrC absorbance at 370nm. HOA are known to be emitted from vehicles and off-road engines and showed strong correlation with BC absorbance at 880nm ($r^2 > 0.75$). For the total absorption at 370nm, multiple linear regression analysis for BC and the four organic aerosol components gave the mass absorption coefficient of HOA ($MAC_{HOA,370nm}$, m^2/g), a measurement proxy of BrC, approximately equal to 1.22 m^2/g. This value is comparable to the reported MAC_{365nm} values of biomass burning organic aerosols. Multiplying the MAC for each component by the mean mass concentration showed that HOA contributed up to ~6% and ~70% of total (i.e., BrC + BC) and BrC absorbance at 370 nm, respectively. Overall, our preliminary results provide field evidence to highlight that vehicular emissions can be an important source of ambient BrC in urban environments. Volatility of ambient BrC and organic aerosols based on the thermodenuder measurements will be discussed.

4CA.6

Over a Decade-long Trend of Concentrations of Ultrafine Particle and Carbonaceous Aerosols at a Traffic Intersection.

YUJI FUJITANI, Katsuyuki Takahashi, Akihiro Fushimi, Shuichi Hasegawa, Yoshinori Kondo, Kiyoshi Tanabe, Shinji Kobayashi, *National Institute for Environmental Studies*

This study showed long-term monitoring data (2004-2017) of particle number concentrations (PNCs: particle size 10-480 nm), size-resolved particulate matter (PM) mass and carbon component, and atmospheric pollutants at the traffic intersection in a metropolitan area in Japan. Comparison was made between atmospheric concentrations of these pollutants at the traffic intersection and the tailpipe PM mass emissions from diesel trucks that passing through the traffic intersection, which is estimated from traffic volumes as a function of emission regulation year and gross weight of trucks obtained by license plate numbers research and giving emission factor of each category.

Decay rate of concentrations of elemental carbon in $PM_{0.1}$ and in $PM_{2.5}$ from 2005 to 2016 were excellently match with reduction rate of PM tailpipe emissions, which indicates tailpipe emission of diesel trucks was dominant source of atmospheric PM and the reduction in atmospheric concentrations directly reflected cleaner of traffic exhausts. From the traffic information, not only reduction of traffic volume during the period but also replacing vehicles that comply with tighter regulation were forward to reduce emissions, which also resulted in better correlations between atmospheric concentrations and tailpipe PM mass emission rather than traffic volume. On the other hand, slower decrease trend of exhaust related PNC than decrease trend of tailpipe PM mass emissions were found.

The positive matrix factorization (PMF) analysis using year-to-year data of PNCs and EC showed the largest contribution factor to EC in $PM_{2.5}$ (about 50% in entire period average) attributed to tailpipe emission from the trucks of emission regulation of 1997-99 because emissions of this regulation vehicles also contribute about 50% to total tailpipe PM mass emission. As for PN particle smaller than 100 nm in entire period of winter, factors that attributed to emissions from 1988-94 regulation vehicles contribute about 50%. The result of PMF analysis, diurnal trend of pollutants, and comparison between summer and winter seasons suggested that high PN in winter morning is due to nucleation of semi-volatile gases mainly emitted from 1988-94 regulation vehicles concurrently in a cold temperature, low wind speed, and low height mixing layer. The implement policy of emission regulation in terms of PM mass did not effective to reduce atmospheric PN as much as PM mass otherwise removing semi-volatile gases which are co-pollutants of PM.

4CA.8

Influence of Aerosol Sources on Atmospheric Black Carbon Absorption Enhancement in the Region of Paris, France.

YUNJIANG ZHANG, Olivier Favez, Francesco Canonaco, Dantong Liu, Jean-Eudes Petit, Tanguy Amodeo, Nicolas Bonnaire, Francois Truong, Jean Sciare, Andre S.H. Prévôt, Valerie Gros, Alexandre Albinet, *INERIS*

Atmospheric black carbon (BC) and light-absorbing organic aerosol (also referred as brown carbon, BrC) have strong effects on the Earth’s climate by absorbing direct solar radiation. To better characterize and quantify these effects, a better understanding of specific underlying mechanisms is needed such as the influence of primary emissions and secondary processes on absorption properties over long-term periods. We report here results of a three-year continuous field observations conducted from March 2014 to March 2017 at a suburban background station (SIRTA) in the Paris region (France). Submicron nonrefractory aerosol species were measured in near real-time using an aerodyne aerosol chemical speciation monitor and were apportioned using Positive Matrix Factorization (PMF) analysis to identify and quantified major organic aerosol (OA) sources. Light absorption properties of BC and BrC were determined by direct measurements using a 7-wavelength aethalometer equipped with the dual spot technology. Co-located 24-h filter-based analyses were performed by thermo-optical technique to quantify the mass concentration of elemental carbon (EC) in $PM_{2.5}$. Absorption enhancement (E_{abs}) of BC-containing particles was obtained using mass absorption coefficient (MAC) ratios calculated between observed (= babs / [EC]) and expected values for uncoated BC. Results showed that the observed Eabs significantly increased with the mass ratio of secondary aerosols to EC, suggesting a strong influence of this secondary components on BC absorption enhancement. Important BrC contribution to the total absorption in the near UV could be attributed to residential wood burning activities in winter and led to significant E_{abs}, independently of internal or external BrC mixing with BC particles. Finally, new findings on summertime aerosol optical properties are also presented and discussed here.

4CA.9

Gaseous and Speciated Particulate Emissions from the Open Burning of Wastes from Tree Pruning. CÉLIA ALVES, Ana Vicente, Estela Vicente, Margarita Evtyugina, María Fernández-Amado, Purificación López-Mahía, *University of Aveiro*

Open-air burning of wastes from tree pruning is a common practice in many regions worldwide. However, this practice degrades air quality and contributes to the greenhouse effect. Aiming at characterizing the gaseous emissions, the smoke from the open burning of vine, olive, willow and acacia branches was sampled into Tedlar bags. In parallel, a high volume sampler was used to collect PM_{10} on quartz filters. The gaseous compounds in Tedlar bags were assessed using a Fourier transform infrared gas analyzer. PM_{10} filters were subjected to the following determinations: ion chromatography, organic and elemental carbon (OC and EC) by a thermo-optical technique, and organic speciation by gas chromatography-mass spectrometry after multisolvent extraction. Emission factors were calculated by stoichiometric considerations using the carbon mass balance method and were as follows (g/kg biofuel, dry basis): 1564-1663 CO_2, 40.6-87.7 CO, 2.06-5.82 CH_4, 0.91-3.73 ethane, < 0.99 ethylene, < 1.80 formaldehyde, 2.70-7.44 OC, 0.32-1.18 EC, and 8.76-20.1 PM_{10}. The modified combustion efficiency (MCE) was always higher than 0.95, suggesting predominance of flaming combustions. MCE was strongly correlated with CO_2 and anticorrelated with CO. From the PM_{10} emitted, water soluble ions represented from 5.3 % (vines) to 12.7 % (acacia). Potassium was the dominant ionic species, accounting for a PM_{10} content from 1.4 to 4.7 % wt. While in smoke from vines and olive combustion the NaCl mass fractions were lower than 0.9 %, higher weight percentages were obtained for willow (3.6) and acacia (6.7). On average, OC accounted for PM_{10} mass fractions of 33.4, 19.3, 32.3 and 36.5 % for willow, acacia, vines and olive, respectively, whist EC represented 5.04, 2.34, 3.53 and 7.32 %, by the same order. Mean levoglucosan (L) mass fractions of 18.1, 13.2, 17.1 and 12.4 mg/g PM_{10} were obtained in samples from the combustion of vines, olive, willow and acacia, respectively. The ratios between this anhydrosugar and its stereoisomers, mannosan (M) and galactosan (G), were within the wide range of values reported for other sources, such as residential biomass burning of hardwood and softwood, forest fire smoke or grass combustion [1]. In the present study, the mean ratios varied from 4.2 and 8.8 for L/M and between 2.3 and 3.7 for L/(M+G). PAH emissions from the combustion of vines and olive branches were one order of magnitude higher than those from acacia and willow. PAHs with 3 or 4-rings were dominant. Among these, the most representative in terms of mass concentrations (µg/g PM_{10}) were: acenaphthylene (27.7-90.9), fluorene (92.7-133), phenanthrene (3.96-281), fluoranthene (17.8-510), pyrene (22.7-511), and chrysene (16.5-545). Benzo[a]pyrene is often used as a surrogate for all carcinogenic PAHs. Its mean mass fractions ranged from 6.51 (willow) to 91.3 (vines) µg/g PM_{10}. Retene, commonly pointed out as a molecular tracer of softwood combustion, was always present (8.23-18.9 µg/g PM_{10}), regardless of the pruning residue. The detection of this polyaromatic in particles from multiple sources raises doubts about its suitability as a tracer for the combustion of conifers [2]. The new databases of the present study can potentially contribute to more accurate source apportionment results when applying receptor models, as well as to improve emission inventories.

Sources and Physicochemical Characteristics of Black Carbon Aerosol in the Southeastern Tibetan Plateau: Internal Mixing Enhances Light Absorption. QIYUAN WANG, Junji Cao, Yongming Han, *Institute of Earth Environment, Chinese Academy of Sciences*

Black carbon (BC) aerosol over the Tibetan Plateau (TP) has important effects on regional climate and hydrological processes. An intensive measurement campaign was conducted at Lulang (~3300 m above sea level), southeastern TP, from September to October 2015 to investigate the sources and physicochemical characteristics of refractory BC (rBC) aerosol. The grand average rBC mass concentration was 0.31 ± 0.55 $\mu g\ m^{-3}$, which is higher than most BC results for the TP. A clear diurnal cycle in rBC showed high values in the morning and low values in the afternoon. A bivariate polar plot showed that rBC loadings were affected by wind speed and direction, which was used to infer the dominant transport directions. The estimated net surface transport intensity for rBC was +0.05 ± 0.29 $\mu g\ s^{-1}\ m^{-2}$, indicating that stronger transport from outside the TP compared with the interior of the TP. Cluster analysis and a concentration-weighted trajectory model indicated that emissions from north India had important contribution to the high rBC, but the effects of internal TP sources cannot be overlooked. The average mass median diameter (MMD) of rBC was 160 ± 23 nm, with smaller size on rainy days (145 nm) compared with non-rainy days (164 nm). The average number fraction of thickly-coated rBC (F_{rBC}) was 39 ± 8%. The FrBC increased with the enhanced O3 mixing ratio from 10:00–14:00 local time, indicating that the photochemical oxidation played an important role in forming rBC coatings. The average rBC absorption enhancement (E_{abs}) was estimated to be 1.8, suggesting that light absorption by coated rBC particles was greater than that for the uncoated ones. The Eabs was strongly positively correlated with the FrBC, indicating an amplification of light absorption for internally-mixed rBC. When rBC core 170 nm. Our study provides insight into the sources and evolution of rBC aerosol on the TP. It is useful for further modelling studies improving precise of evaluating the radiative forcing of carbonaceous aerosols in this area.

Characteristics of Pollutant Emissions from Typical Coastal and Riverine Ships in China. XIANG DING, Qing Li, Di Wu, Jianfeng Sun, Xianmang Xu, JianMin Chen, *Fudan University*

China accounted for 70% of the world's top 10 ports in 2015, according to the World Shipping Council. The ship emission has become one major air pollution source in the coastal and riverine areas of China. To our knowledge, field study has rarely been conducted, especially at emissions from CVs (coastal vessels) and RVs (riverine vessels) in China. Therefore, the characteristics of gaseous (CO, SO_2, NO, NO_2, NO_X, NMVOCs) and particulate matters (PMs, number and mass size distributions) emissions regularly sailing on the China East Sea and Yangzi river were investigated in this study. Effects of running condition (engine speed: 400~640 rpm) and fuel quality (HFO: 2.07% of fuel S, and MDO: 0.12% of fuel S) on gaseous and $PM_{2.5}$ emission factors from CVs and RVs were systematically compared.

The emission factors of NO_X, SO_2, CO, NMVOCs and $PM_{2.5}$ from RVs operated with MDO under different load conditions and CVs operated with HFO and MDO under same load conditions varied in the range of 50~80, 10~35, 8~23, 0.05~0.5 and 0.4~3.2 $g{\cdot}(kg\ fuel)^{-1}$. This study found that the emission of CO and NO_X were determined by engine (RVs and CVs) and its operating condition, while emissions of SO_2, NMVOCs and $PM_{2.5}$ were influenced by both fuel quality and engine operating condition. The particle number size distribution of in plumes of RVs were dominated by particles in the accumulation mode with peak at 70–90 nm, while the highest number concentrations increased from ~10^7 to ~10^8 cm^{-3} when the engine speed increased from 400 to 640 rpm at a 75% of full engine load. The mass ratio of fine particles ($PM_{2.5}$) in total suspended particles was about 82–87%. The $PM_{2.5}$ was dominated by organic carbon (OC) and elemental carbon (EC). The percentages of EC increase from 19% to 61% with increasing engine speed from 400 rpm to 640 rpm in 75% loads, while those of OC decrease from 51% to 23%. The variation of EC/OC percentages is owing to that an increase of engine speed results in increase of fuel usage and flue temperature, as well as decrease of air-to-fuel ratio. Additionally, the fractions of SO_4^{2-} exhibit much less variation with engine speed.

4CA.12

Comprehensive Assessment of Carbonaceous PM2.5 in Malaysia during Haze Events Influenced by Indonesia Peatland Fire and Non-Haze Period. KURITA HIROKI, Fujii Yusuke, Tohno Susumu, Saito Nozomi, Kamiya Yuta, Takayuki Kameda, Regina Hitzenberger, Haller Theresa, Ikeda Kazuhiro, Sakai Nobumitsu, Sulong Nor Azura, Mohd Talib Latif, Ohura Takeshi, *Kyoto University*

Biomass burning (BB) is one of the major sources of PM2.5 in Southeast Asia. Especially, haze from peatland fire in Indonesia frequently causes serious environmental problems such as human health impact, visibility impairment and regional climate change in ASEAN countries during dry season. Carbonaceous components are the dominant species of BB aerosols and their comprehensive characterization is indispensable to assess their effects on environment or conduct effective source apportionment. In this study, twenty four-hour PM2.5 filter samples were obtained by annual sampling in Kuala Lumpur, Malaysia (sampling site: 3° 8′ 20.4′′ N, 101° 41′ 12.6′′ E, 56 m above sea level) from June 2015 through May 2016 with a total of 139 samples. Detailed information of sampling site in this study has been provided in the previous report (Sulong et al., Sci. Total Environ., 601-602, 556-570, 2017). The samples were subjected to chemical analysis of elemental carbon (EC), organic carbon (OC), water-soluble organic carbon (WSOC), carbon content of humic-like substances (HULIS-C), polycyclic aromatic hydrocarbons (PAHs) and their derivatives, other biomass pyrolysis-derived compounds, and components of biogenic secondary organic aerosols (SOA). EC and OC were analyzed by a thermal-optical reflectance method with IMPROVE_A protocol. Black carbon (BC) and brown carbon (BrC) were also determined by an integrating sphere method (see Wonaschütz et al., Environ. Sci. Technol., 43, 1141-1146, 2009).

PM2.5 mass concentrations ranged from 7.4 to 241 μg m-3 with an annual average of 38.2 μg m-3. OC was the dominant component of PM2.5 and the concentrations varied from 1.3 to 40 μg m-3. EC concentrations were in the range of 0.3 to 6.1 μg m-3, while BC concentrations were from 0.22 to 2.4 μg m-3. There was significant discrepancy between EC and BC concentrations of the most samples collected in the peatland fire season (August – October), however, EC concentrations agreed well with those of BC during non-fire periods (June, July, and November – May). BC concentrations was virtually constant of around 2 μg m-3 for the samples whose EC concentrations were higher than 3 μg m-3, or concentrations of levoglucosan, a typical BB marker were higher than 0.5 μg m-3. This result suggests that higher concentrations of BB components have influence on the thermogram of the EC/OC analysis and contribute to the positive potential bias in EC determination resulting from the slipping of residual OC into the He/O2-mode and its potential evolution after the split point by maximizing the evolution and/or pyrolysis of OC at high temperature in the He-mode (Cavalli, F. et al., Atmos. Meas. Tech., 3, 79-89, 2010). Effect of HULIS-C is also discussed. We have quantified 20 PAHs, 35 nitro-PAHs (NPAHs), 20 oxygenated PAHs (OPAHs) and 20 chlorinated PAHs (ClPAHs) in PM2.5. Annual average total concentrations of PAHs, NPAHs, OPAHs and ClPAHs were 1.37, 0.70, 1.19 and 0.037 ng m-3, respectively. Total concentrations of each PAHs showed remarkable increase for haze samples (PM2.5 concentration is larger than 100 μg m-3) compared with non-haze samples (PM2.5 concentration is less than or equal to 30 μg m-3). Regarding biogenic SOA tracers, β-caryophyllinic acid (β-caryophyllene ozonolysis product) concentrations of haze samples were much higher than those of non-haze samples.

4CA.13

Contrasting Temporal and Spatial Variation of Atmospheric Carbonaceous Aerosols during a Year-Long Measurement in Central India. SHAMSH PERVEZ, Rakesh Sahu, Suresh Tiwari, A.S. Panicker, Rajan K. Chakrabarty, Judith Chow, John Watson, Yasmeen F. Pervez, *Pandit Ravishankar Shukla University, Chhattisgarh, India*

Air pollution is now serious health concern in developing countries including India and has been responsible for adverse effects on human health. The study, presented here, describe the spatiotemporal variability in year-long measurements of ambient $PM_{2.5}$ and associated component of carbonaceous matter in rural, industrial and urban environments of Central India during October 2015 to September 2016. Weekly $PM_{2.5}$ aerosols sampling were carried out (gravimetrically) using a set of two parallel $PM_{2.5}$ cut-off impactors consisted MiniVol air samplers, positioned in an urban, industrial and rural environments of Raipur, Bhilai and Kosmarra (a village of Dhamtari District), Chhattisgarh, India. Urban site was also used to measure day and night time ambient $PM_{2.5}$ to evaluate the impact of meteorological parameters on occurrences of $PM_{2.5}$ masses. $PM_{2.5}$ deposited on quartz filters were analyzed for temperature resolved fractions of carbonaceous matter using Thermal/Optical carbon analyzer (DRI Model 2001) by following IMPROVE_A Protocol. The annual average $PM_{2.5}$ mass concentrations of rural, urban and industrial sites found to be ~2 to 5 folds higher than the Indian National Ambient Air Quality Standard (NAAQS). Higher occurrences of OC and EC in $PM_{2.5}$ was observed in the winter season, compared to those measured in the summer and post-rainy. Similarly, OC and EC concentrations were found to be higher at night time than those observed for daytime in the urban site. On comparing with reported values for other Indian locations, Raipur (urban) and Bhilai (urban-industrial) sites have shown the highest percentage of Total Carbonaceous Aerosols (TCA) in ambient $PM_{2.5}$. The annual mean ratio of OC/EC has been found to be 3.50 ± 1.76 (range 2.16 to 7.84) and 3.94 ± 0.98 (range 1.63 to 5.42) in urban and rural sites, respectively; indicates the dominance of biomass burning (BB) and incomplete combustion (IC) in industrial processes in occurrence of higher carbonaceous aerosols in ambient air. The average char/soot ratios are observed to be 3.65 ± 2.65, 1.77 ± 0.98 and 1.93 ± 0.62 for urban, rural and industrial sites, respectively. Contribution of secondary organic aerosol (SOA) to ambient OC and thermal fractions of OC and EC have also been investigated for rural, industrial and urban sites and analysis is in progress. The details results will be presented during the conference.

Metrology for Light Absorption by Atmospheric Aerosols: The EMPIR Black Carbon Project. Eija Asmi, Joel Corbin, Volker Ebert, Konstantinos Eleftheriadis, François Gaie-Levrel, Martin Gysel, Thomas Müller, Andreas Nowak, Konstantina Vasilatou, Ernest Weingartner, PAUL QUINCEY, *NPL*

Black carbon (BC) is widely recognized as the foremost particulate absorber of solar radiation in the atmosphere and has been associated with the detrimental health effects of air pollution. To monitor BC concentrations, the atmospheric-science community has developed an array of technologies based on light absorption measurements. These absorption measurements are typically reported as mass concentrations of Equivalent Black Carbon (EBC) by using a standard mass absorption cross-section at a given wavelength. However, there is currently a lack of SI traceability for such absorption measurements. In addition, the most common field instruments measure EBC after depositing aerosol particles onto a filter, which introduces complex uncertainties and a need for standardized calibration methods.

The EMPIR Black Carbon project, *Metrology for light absorption by atmospheric aerosols (2017 – 2020)*, aims to establish SI traceability for atmospheric aerosol light absorption measurements, based on filter-free methods such as extinction-minus-scattering, photoacoustic spectroscopy, or photothermal interferometry, as well as standardised calibration routines for filter-based instruments. To this end, its specific objectives are to (1) develop a traceable and primary method for measuring aerosol absorption at specific wavelengths, with defined uncertainties and (2) recommend well-characterized reference aerosols suitable for challenging filter-based instruments. Further co-benefits of this work are (3) the establishment of a set of well-defined physical parameters for the traceable quantification of EBC concentrations and (4) the development of a validated method for the in-situ calibration of filter-based field instruments.

This presentation aims to motivate and summarize the goals of the EMPIR project, which is currently in its early stages, in order to encourage and invite contributions from the community.

4CA.17

Usefulness of Stable Carbon Isotope and Other Chemical Tracers to Distinguish between Primary and Secondary Carbonaceous Sources of PM2.5 Particles over a National Park in Central India. SHILPI SAMIKSHA, Ramya Sunder Raman, *Indian Institute of Science Education and Research, Bhopal*

Carbonaceous aerosols were investigated by measuring the stable carbon isotopic ratio, $\delta^{13}C$ in bulk $PM_{2.5}$ particles. In this study, ambient $PM_{2.5}$ samples were collected over Van Vihar National Park in Bhopal, central India over a period of two years (01 January, 2012 to 31 December, 2013). 12 hour integrate samples were collected on to Teflon, Nylon, and quartz fiber filter substrates. Punches of the quartz fiber filters were analyzed for organic and elemental carbon (OC/EC) using a thermal-optical-transmittance/reflectance (TOT-TOR) analyzer operating with a 632 nm laser diode.

Punches of the quartz filters were further analyzed for concentrations of total carbon (TC) and their $\delta^{13}C$ were measured using elemental analyzer (Flash 2000) interfaced to isotope ratio mass spectrometer (EA-IRMS). The CO_2 produced was introduced into a MAT 253 isotope ratio mass spectrometer (IRMS) via a Conflo IV interface to determine the carbon isotopic ratio. Standard (Acetanilide and CH-3 cellulose) were measured after every 4 samples and every tenth sample was analyzed in duplicate. Duplicates were analyzed such that they covered the entire concentration range of the samples. A routine precision of ~ ± 0.1‰ was obtained.

This study will present preliminary results on the seasonal variations $\delta^{13}C_{TC}$ in $PM_{2.5}$ particles collected over the study site. We also investigate the relationships between $\delta^{13}C_{TC}$ concentration and the concentrations of other chemical tracers (mono and di-carboxylic acids, K^+), their seasonal variations, and associations with air parcel back trajectories. These relationships will be used to estimate the relative importance of primary and secondary organic aerosols at the study location. Further, isotope-mixing models (e.g., ISOSOURCE) will also be used for organic aerosol source characterization.

4CA.18

Source Apportionment of Fossil Fuel and Biomass Burning Black Carbon (Bc) in the Milan Metropolitan City and Bareggio Sub-Urban Area Contrasting Locations. AMIRHOSEIN MOUSAVI, Mohammad Sowlat, Ario Ruprecht, Constantinos Sioutas, *University of Southern California*

In the current work, spatial and temporal variation of black carbon (BC) were evaluated at two sites, including Milan, a metropolitan area primarily impacted by urban emissions, and Bareggio, a sub-urban area, from July to October 2017. Using the Equivalent Black Carbon (EBC) model, sources of BC were apportioned using the BC measurement data from seven-wavelength (AEE33) and two-wavelength (AEE51) aethalometers for Milan and Bareggio, respectively. Result indicated that BC concentrations are ranging from 0.75-1.65 $\mu g.m^{-3}$ in Bareggio with a peak in July and 1.05-1.56 $\mu g.m^{-3}$ in Milan with the highest values in October. In addition, MAC values for both 370 nm (7.2±0.6 $m^2.s^{-1}$) and 880 nm (16.2±0.8 $m^2.s^{-1}$) wavelengths showed a consistent temporal trend and between the sites with slightly higher values for Bareggio. Moreover, fossil fuel combustion contributions to the total BC concentrations (ranging from 72% in Bareggio to 96% in Milan) are relatively higher than those of biomass burning (ranging from 10% in Milan to 26% in Bareggio). For fossil-fuel-originated black carbon (BC_{ff}), major peaks were observed during the traffic rush hours, whereas the contribution of black carbon that originated from biomass burning (BC_{bb}) was maximum during nighttime reaching values as high as 25-30% of total BC concentrations in Bareggio site. Moreover, results of the ongoing measurements for the cold season of the study will also be presented to compare the levels and BC_{ff}% and BC_{bb}% across different seasons.

4CA.19

Wintertime PM2.5 in the Kathmandu Valley and Terai Region of Nepal. MD. ROBIUL ISLAM, Nita Khanal, Khadak Mahata, Siva Praveen Puppala, Narayan Babu Dhital, Michael Giordano, Benjamin Werden, Anobha Gurung, Arnico Panday, Peter DeCarlo, Elizabeth Stone, *University of Iowa*

Airborne particulate matter (PM) adversely impacts human health through respiratory and cardiopulmonary diseases. Kathmandu Valley and the Indo-Gangetic Plain (IGP) are experiencing serious PM pollution problems. PM pollution in these regions is worse in the winter months (December – February) when regional haze or "fog" events occur. This poster will present preliminary results from the second Nepal Ambient Monitoring field campaign on the levels, composition, and sources of $PM_{2.5}$ and PM_{10} in the Kathmandu Valley and in northern IGP during wintertime. PM samples were collected at Ratnapark (in the Kathmandu Valley at 1300 m a.s.l.), Dhulikhel (east end of the Kathmandu Valley at 1600 m a.s.l.), and Lumbini (in the northern IGP at 100 m a.s.l.) for 7-10 days at each site. The samples were collected during daytime and nighttime periods spanning December 20, 2017 - January 27, 2018. PM mass concentrations were determined and chemical analysis were conducted includes to determine levels of organic carbon (OC) and elemental carbon (EC), water soluble inorganic ions, and organic species. Organic speciation focused on molecular markers (a chemical species that is specific to an aerosol source) to gain insight to the sources of organic aerosol (i.e. biomass burning, garbage burning, fossil fuel combustion, secondary organic aerosol, etc.). These data will be used for the purpose of identifying primary and secondary sources of PM and to estimate source contributions to $PM_{2.5}$ and OC through chemical mass balance (CMB) source apportionment.

4CA.20

Measurement of Speciated Gaseous and Particulate Organic Nitrates in Urban Atlanta using FIGAERO-HR-ToF-I-CIMS.

MASAYUKI TAKEUCHI, Gamze Eris, Taekyu Joo, Yunle Chen, Weiqi Xu, Dao Huang, Gabriela Saavedra, Seongshik Kim, Dong Gao, Rodney J. Weber, Yele Sun, Michael Walker, Brent Williams, Jenna Ditto, Drew Gentner, David Tanner, Greg Huey, Nga Lee Ng, *Georgia Institute of Technology*

Owing to the semi-/low-volatile nature of organic nitrates and their implication for the budget of reactive nitrogen species (i.e. NO_x) and ozone formation, atmospheric organic nitrates have been receiving increased attention in the atmospheric research community. Previous field studies using online instruments, such as Thermal-Dissociation Laser-Induced Fluorescence (TD-LIF) and Aerosol Mass Spectrometer (AMS), have demonstrated the ubiquitous presence of organic nitrates across different continents and in different environments. However, there is limited understanding at the molecular level of such organic nitrate species and the seasonal effect on their chemical composition. Additionally, the dominant source (e.g. daytime vs. nighttime, primary vs. secondary, etc.) and the fate of organic nitrates are not well understood. In this study, the Filter Inlet for Gases and AEROsols (FIGAERO) coupled to High Resolution Time-of-Flight Iodide Chemical Ionization Mass Spectrometer (HR-ToF-I-CIMS) was used to measure speciated gaseous and submicron particulate organic nitrates at the Jefferson Street site in Atlanta, GA, USA which is an urban site in the Southeastern Aerosol Research and Characterization (SEARCH) network, using. Measurements were conducted in summer 2017 and winter 2018. Preliminary results show that C_{4-5} and C_{8-10} organic nitrates represent a significant fraction of total organic nitrates in summer, suggesting the important role of biogenic volatile organic compounds such as isoprene and monoterpenes. However, C_{8-10} organic nitrate species dominates over C_{4-5} organic nitrates in winter due to reduced isoprene emission. In addition, we observed high molecular weight compounds, tentatively assigned as C_{20} organic mono-/di-nitrates, in the particle-phase that exhibit a clear diurnal pattern peaking little after midnight. These high molecular weight compounds are also detected in laboratory chamber experiments of monoterpene NO_3 oxidation, implying a significant contribution of NO_3 chemistry to the formation of particulate organic nitrates in winter. Bulk volatility distributions of ambient organic nitrates derived from FIGAERO thermogram data are presented and compared with those of laboratory-generated organic nitrate aerosols to confirm the contribution of NO_3 oxidation to organic nitrate aerosol formation. Lastly, the effects of ambient temperature, relative humidity, NO_x level, and the level of various volatile organic compounds on the ambient concentrations of speciated and bulk organic nitrates will be discussed.

4CA.21

Measurements of Dry and Wet Black Carbon Deposition over a Grassland. GAVIN MCMEEKING, Ethan Emerson, Joseph Katich, Joshua P. Schwarz, Delphine Farmer, *Handix Scientific*

The atmospheric lifetime of black carbon (BC), an important light-absorbing aerosol component, is controlled by wet and dry deposition, which are poorly constrained by observations. We apply a single particle soot photometer (SP2), which measures the mass of refractory BC in particles using laser-induced incandescnce, to measure surface-atmospheric exchanges of BC via eddy covariance. Measurements were performed at the DOE ARM Southern Great Plains site in Oklahoma during summer. Wet deposition measurements of BC were also performed by analyzing collected precipitation samples through a combination of nebulization followed by SP2 measurement. We report on the relative importance of dry and wet deposition processes during the study, and estimate a BC lifetime with respect to each process. Additional eddy covariance measurements performed in other locations are also discussed.

4CA.24

Equivalent Black Carbon (EBC) Measurement at a Regional Background Site in Central Europe Using a Multiple Wavelength Aethalometer: Variability and Source Apportionment. SALIOU MBENGUE, Norbert Serfozo, Jaroslav Schwarz, Nadežda Zíková, Adéla Holubová Šmejkalová, Ivan Holoubek, *Global Change Research Institute, CAS, Brno 60300, CZ*

Equivalent Black carbon (EBC) is a primary carbonaceous aerosol emitted from a variety of combustion related sources. It is recognized to play an important role on adverse public health and in the Earth's climate system. Although measurements at background areas are important for better characterizing and understanding the influence of anthropogenic emissions on climate forcing and health effect, scarce studies have been reported in Eastern Central Europe using real-time EBC measurements. This study focuses on the seasonal, diurnal and weekly trends of EBC at a regional background site in Central Europe. Our aim is to identify the potential sources of EBC, especially the influence of fossil fuel and biomass burning.

The EBC in PM_{10} was monitored at NAOK (National Atmospheric Observatory Košetice, 49°35'N, 15°05'E), central Czech Republic. Measurements were performed from 2012 to 2017 at ground base (4 m) with a 5 min time resolution using a seven wavelength aethalometer (Model AE31, Magee Scientific). The EBC data have been corrected for loading effect, and Delta-C variable (EBC370nm-EBC880nm) was calculated.

Preliminary results show that concentrations of EBC are higher in winter than in summer, which could be related to the variability in sources intensities and meteorological conditions. The wavelength dependence of light absorption by collected aerosols will be investigated to identify the potential sources of EBC at the rural site. The diurnal cycles of EBC in the near-ultraviolet (370 nm) and in the near-infrared (880 nm) spectral regions are compared for winter and summer. The diurnal cycles are stronger in winter than in summer with lower concentrations observed at noon time when the mixing height reaches a peak (i.e. higher dispersion of pollutants). In summer, EBC emission could be mostly attributed to fossil fuel combustion, which is consistent with the smaller difference between diurnal profiles of λ_1 and λ_6. Delta-C values, a proxy for biomass burning is more pronounced in winter, which is consistent with the increased emissions from wood burning.

Furthermore, correlations will be examined between EBC and other parallel measurements of atmospheric pollutants (OC/EC, CO, $_{NO2,}$ SO_2) at NAOK. The influence of fossil fuel and biomass burning will be investigated deeper using Ångström absorption exponent and Delta-C.

4CA.25

Estimating Aerosol Light Absorption from Filter-based Spectrophotometer Measurements. APOORVA PANDEY, Nishit Shetty, Rajan K. Chakrabarty, *Washington University in St Louis*

Filter-based instruments, such as the aethalometer, particle soot absorption photometer and UV-vis spectrophotometer, estimate aerosol light absorption by measured attenuation through an aerosol loaded filter. The conversion of attenuation coefficient to absorption coefficient is subject to several measurement artifacts, including multiple scattering of light by the filter and "shadowing" effects from increasing loading of aerosols. In general, the magnitude of these artifacts depends on the properties of the filter substrate, the aerosol optical loading, and the aerosol single scattering albedo (SSA). The relationship between aerosol light absorption and filter based transmittance or reflectance measurements needs to be established for each instrument and filter substrate combination. In this work, we evaluate the use of Teflon membrane filters in a UV-visible spectrophotometer to estimate absorption coefficients. Particles with SSA values ranging 0.4-0.99 were generated using flaming/smoldering phase combustion of a variety of biomass types. Aerosol samples were collected on Teflon and quartz fiber filters in parallel with in situ measurements of absorption and scattering coefficients using multi-wavelength Photoacoustic Spectrometers with integrated nephelometers at 375, 405 and 532 nm. A high-resolution UV-vis spectrophotometer equipped with an integrating sphere was used to measure transmittance and reflectance spectra from the Teflon filters. An attenuation value was calculated using the above measurements. The ratio of the aerosol absorbance (calculated from photoacoustic measurements) and the filter attenuation is commonly designated filter correction factor; this factor was positively correlated with the attenuation (loading effect), but showed an inverse relationship with SSA. We found that for a wide range of aerosol properties (i.e. SSA), the absorbance can be conveniently expressed as a simple function of the attenuation measurements, with no need of additional parameters. The behavior of the aerosol-filter system was also modeled by applying the solution of two-stream model of radiative transfer in one dimension to a two-layer approximation of the system. The predicted relationship between absorbance and attenuation was consistent with the experimental data.

4CA.26

Brown Carbon Aerosol Observed in the Remote Atmosphere. LINGHAN ZENG, Rodney J. Weber, Aoxing Zhang, Yuhang Wang, Eric Scheuer, Jack Dibb, Jose-Luis Jimenez, Pedro Campuzano-Jost, Joshua P. Schwarz, Kathryn McKain, Eric Apel, *Georgia Institute of Technology*

Organic aerosols (OA) have long been thought to only scatter sun light and thereby cool the climate. However, a portion of organics, so called brown carbon (BrC) absorb strongly at shorter wavelengths. BrC is emitted by the incomplete combustion of fuels, especially biomass, or produced from secondary formation processes. BrC has been found to be ubiquitous in continental air masses. In both ambient and laboratory studies, as BrC ages, it is observed to become less effective as a light-absorber due to photo-bleaching effects. The global radiative impact of BrC is difficult to assess with models owing to the large uncertainties in its emissions and chemical processing in the atmosphere. Lack of global scale BrC data sets limits our understanding of BrC processing and precludes meaningful model simulation assessments. The NASA Atmospheric Tomography (ATom) mission provided an opportunity to make measurements of BrC in the remote atmosphere over global extents reaching near pole-to-pole along the central Pacific and Atlantic oceans during different seasons. During ATom, filters loaded with ambient aerosol sampled with the NASA DC-8 research aircraft were extracted into water and methanol, sequentially, and the light absorption of the solutes was determined via long optical path capillary measurements. The results provide the first data set of BrC on a global scale. Generally, BrC concentrations are found to be very low in most of the remote atmosphere, and detectible levels were only found in specific regions, including the mid-Atlantic downwind of African or South American fires and in regions of the Arctic. Further data analysis, including comparisons with predictions from the Community Atmosphere Model version 5 (CAM5) of the Community Earth System Model (CESM) are used to better understand the sources, atmospheric loss and transport processes, and radiative impacts of BrC on a global scale.

Fourier-transform Infrared Determination of Organic and Elemental Carbon: Anomalous Samples and What They Tell Us about Composition and Sources. ANN DILLNER, Andrew Weakley, Bruno Debus, Satoshi Takahama, *University of California, Davis*

Several studies have demonstrated that thermal optical reflectance (TOR) OC and EC in fine aerosol can be predicted from Fourier transform infrared (FT-IR) spectra of aerosol samples collected on polytetrafluoroethylene (PTFE) filters. Calibrations for OC and EC are developed using partial least squares regression and provide equivalent OC and EC mass with accuracy and precision comparable to TOR. For most samples, one calibration model developed from samples from multiple sites is needed to predict OC and EC across sites and seasons. Here, we discuss cases in which multi-level modeling is needed for high quality predictions. For example, in the Chemical Speciation Network (CSN), which provides speciated particulate matter concentrations at urban sites, samples from one site with (presumably) distinctive EC sources are not well predicted by the calibration developed for all samples. To accurately predict EC on these anomalous samples, “ordinary” EC is distinguished from more “anomalous” EC using the sample’s FT-IR spectrum and a classification algorithm (partial least squares discriminant analysis). Samples collected from the Elizabeth, NJ sampler, located near a major tollway, often contained anomalous EC. Further analysis of FT-IR spectra and TOR fractions suggested that Elizabeth samples likely contained elevated levels of EC from fresh diesel exhaust as evidenced by the use of organic nitrogen functional groups for prediction, very low average OC/EC, and minimal charring during TOR speciation. FT-IR EC from the other eight sites in this study was predominately determined by aliphatic C-H, C=C aromatic, and functional groups associated with oxidation. Two calibration models were developed, one for ordinary and one for anomalous spectra. Classified spectra were allocated to their associated calibration resulting in a significant reduction in prediction error (30% to 21%; $p<0.05$). This study provides insights into appropriate tools for accounting for significantly different chemical compositions at different sites and into the character of carbonaceous aerosol at heavily diesel impact sites as compared to more typical urban environments. Additional examples from the Interagency Monitoring to Protect Visual Environments (IMPROVE) network will be presented.

4CA.28

Particulate and Gas Phase Separation in Simultaneous Sampling of Combustion Byproducts: New Insights into Chemical Composition by Mass Spectrometric Analysis. Jennifer Noble, Linhdan Ngo, Dumitru Duca, MARIN VOJKOVIC, Abd Raouf Ikhenazene, Cornelia Irimiea, Guillaume Lefevre, Alessandro Faccinetto, Claire Pirim, Yvain Carpentier, Bertrand Chazallon, Nicholas Nuns, Jerome Yon, Eric Therssen, Cristian Focsa, *Université de Lille*

Combustion is the largest anthropogenic source of aerosol particles, accompanied by significant gas phase byproducts. Combustion soot particles can have a direct or indirect effect on climate that gives rise to important consequences for both atmospheric radiative forcing and cloud formation and lifetime. Although many studies have been conducted to characterise soot particles (e.g. Parent et al. 2016), more extensive investigation of their composition and molecular structure is required in order to better understand the role of particulate and gas phase combustion byproducts in atmospheric physicochemical processes.

In this study, a new simultaneous sampling method was developed for combustion byproducts in the particulate and gas phases. The experimental protocol was verified using a Combustion Aerosol Standard (CAST) burner supplied with various propane-air mixtures. Combustion byproducts were collected on two quartz microfibre filters in series. Firstly, a “front filter” was used to collect particulate matter and, secondly, a “back filter” covered with carbon black adsorbed gases that passed through the front filter, following the principle of Faccinetto et al. (2011).

An analytical approach combining micro-Raman and micro-Fourier Transform Infrared spectroscopies with Secondary Ion Time-of-Flight Mass Spectrometry (ToF-SIMS) and Two-step Laser Mass Spectrometry (L2MS) was adopted, in order to characterise the structural and chemical properties of the sampled particulate and gas phases. The custom built L2MS setup allows a detailed chemical analysis of trace amounts of deposited particles at the molecular level, revealing the presence of chemical classes such as aliphatics, aromatics, nitrogenated- /oxygenated-hydrocarbons, organosulfates and metals. For combustion soot, the degree of aromaticity, determined by the relative abundance of polycyclic aromatic hydrocarbons (PAHs), is decisive in determining its physicochemical properties. The L2MS technique is especially well adapted for PAH detection. ToF-SIMS has high sensitivity for both inorganic and organic species, notably the Cn- ion series, a proxy for elemental carbon. Vibrational spectroscopies provide complementary information about the chemical composition and structure of soot by probing the vibrational modes of its composite molecules (Ess et al. 2016).

Our combined mass spectrometry and vibrational spectroscopy studies suggest that the gas and particulate phases of combustion byproducts are sampled effectively using the chosen methodology, and confirm that they have significantly different chemistry. In the samples used to validate the method, the mass distribution of PAHs is found to vary significantly, not only with operation point of the CAST burner but also between the gas and particulate phases. Principal component analysis allowed discrimination between different working points of the burner, in both the particulate and gas phases. The gas phase of all sampled working points contains lower mass PAHs than the particulate phase and, perhaps surprisingly, the mass distribution of gas phase PAHs varies with the richness of the fuel-air mixture.

Following successful validation of the sampling and analysis protocol, combustion byproducts were sampled with the same double-filter method in a kerosene flame (with direct interest for the aeronautical domain). We present a comparison between CAST and flame byproducts in the particulate and gas phases.

Apportionment of Black Carbon to Fossil Fuel and Biomass Burning Sources in the Lower Fraser Valley, British Columbia: Impact of 2017 Wildfires on Local Air Quality. Robert Healy, Geoff Doerksen, UWAYEMI SOFOWOTE, Yushan Su, Jerzy Debosz, Michael Noble, Cheol H. Jeong, Jon M. Wang, Nathan Hilker, Greg J. Evans, Anthony Munoz, *Ontario Ministry of the Environment and Climate Change*

One year Aethalometer datasets collected concurrently at six sites in the Lower Fraser Valley, British Columbia from September 2016 through August 2017 have been analyzed in order to investigate the relative importance of fossil fuel and biomass burning contributions to black carbon (BC) in the region. The sampling sites are located in North Vancouver, Richmond, South Burnaby, Port Moody, Abbotsford and Chilliwack. These sites experienced annual mean BC mass loadings in the range 0.3-0.7 $\mu g\ m^{-3}$, with the highest concentrations observed in Vancouver and the lowest in Chilliwack, a small city located approximately 100 km east of Vancouver. BC was apportioned to fossil fuel and biomass burning sources at hourly resolution using the dual-wavelength optical model approach, first incorporating assumed alpha values of 0.90 and 2.09, respectively. However, applying a value of 2.09 was found to significantly underestimate the fraction of BC from biomass combustion (BC_{bb}) during a prolonged wildfire smoke event which persisted for 10 days in August 2017 and impacted air quality severely in the region. Hourly resolution $PM_{2.5}$ concentrations in excess of 100 $\mu g\ m^{-3}$ were recorded several times at multiple sites during this event and mean ambient $PM_{2.5}$ concentrations for the 10 day period were up to eight times higher than mean concentrations for the remainder of the summer. Using a difference approach to estimate the BC mass associated with the wildfire plume enabled an optimization of the alpha value for wildfire aerosol at each site. Similar wildfire alpha values were determined at all six sites using this approach 1.40 ± 0.10, which is sensible considering that all sites were influenced simultaneously by the same plume. The highest hourly resolution wildfire BC_{bb} mass loadings were observed at Chilliwack (7.3 $\mu g\ m^{-3}$), which is situated closest to the wildfire source regions, identified using conditional probability function and quantitative transport bias analyses. For the Lower Fraser Valley sites investigated, approximately 34-45% of total summertime exposure to BC and 64-86% of total summertime exposure to BC_{bb} occurred during the 10 day wildfire event. On an annual scale, however, residential wood combustion is estimated to be a larger contributor to ambient BC than wildfires at every site.

Source Apportionment and Variability of Submicron Organic Aerosol from Year-long Near Real-time Measurements Over an Urban Mediterranean Area. Aikaterini Bougiatioti, IASONAS STAVROULAS, Despina Paraskevopoulou, Georgios Grivas, Pavlos Zarmpas, Eleni Liakakou, Evangelos Gerasopoulos, Nikolaos Mihalopoulos, *National Observatory of Athens*

Organic aerosol (OA) represents a large fraction of submicron aerosols worldwide, especially in urban areas. During the winter season, wood combustion is one of the major sources of OA in Europe (Puxbaum et al., 2007) which apart from contributing to the production of primary aerosol, is also responsible for significant secondary organic aerosol formation (Heringa et al., 2011). The economic recession in Greece during the past seven years has caused a deceleration of industrial activity and limitation of vehicular circulation (Paraskevopoulou et al., 2014). Strong correlation between economic indicators and several pollutants levels, reveal that this recession has resulted in significantly lower levels of pollutants in many large cities of Greece (Vrekoussis et al., 2013). Nevertheless, this crisis has lead residents to the “cheaper” solution of uncontrolled wood and biomass burning for domestic heating purposes, causing significant air quality deterioration. During summer all concentration levels are significantly lower and sources are more regional than local.

This study focuses on high temporal resolution chemical composition measurements performed in downtown Athens during three different winter periods and also a complete year, in order to identify the different sources of organic aerosol seasonally. It occurs that overall, organic aerosol represents half or even more of the total PM1 mass, with concentrations during all studied winters reaching up to 240 μg m-3. During the cold period 5 different factors of OA are identified, namely hydrocarbon-like OA (HOA), contributing an average of 15%, cooking OA (COA) with 9% contribution, biomass burning OA (BBOA) with 12%, a highly oxidized, low volatility OA factor (LV-OOA) with 34% and a semi-volatile OA (SV-OOA) contributing the remaining 30%. This SV-OOA has high affinity with biomass burning tracers, denoting its provenance from the fast oxidation of primary combustion sources. If the provenance of SV-OOA is combined with the primary BBOA and primary HOA from central heating systems, it is clear that almost half of the organic aerosol during wintertime in Athens originates from combustion activities.

During the warm period, 4 different factors of OA are identified, the same as before except for the primary BBOA. HOA contributes around 5.5% to the total organic fraction, COA 12%, SV-OOA around 38% and the rest 44.5% is attributed to LV-OOA. SV-OOA during summertime may be derived either from the oxidation of primary COA or from biogenic sources. Nevertheless it is clear that during the summer period the prevailing source of OA is the much oxidized OA, which has a more regional character and is linked to secondary aerosol formation.

Backtrajectory analysis, using the Potential Source Contribution Function (PSCF) method, and combination of pollutant concentrations with wind direction and speed, through Non-Parametric Wind Regression techniques were applied, in order to determine the local or regional origins of atmospheric pollution in downtown Athens throughout the year.

4CA.31

Impact of Organic Aerosol Partitioning on U.S. Particle Emission Factors. BENJAMIN MURPHY, Christos Efstathiou, Havala Pye, *United States Environmental Protection Agency*

Direct emissions of particulate-phase organic and inorganic compounds contribute the majority of near-field particle mass from combustion sources, especially in urban areas. For sources with substantial organic fractions (e.g. vehicles, fires, power plants, etc), previous studies have demonstrated the importance of considering reversible partitioning of organic compounds between the gas- and particulate-phases when linking laboratory/field measurements with predictions of ambient concentrations, from e.g. chemical transport models (see e.g. Murphy et al., 2017). For example, studies that characterize the emission factors or composition of particles from specific sources may be performed at much higher concentrations than what is relevant for the atmosphere and their emission factors must be adjusted to take nonlinear evaporation processes into account.

Any of several potential pitfalls could occur when combining emission factor databases (e.g. National Emissions Inventory, NEI), speciation databases (e.g. SPECIATE), emission models (e.g. MOVES, SMOKE) and chemical transport models (e.g. the Community Multiscale Air Quality model, CMAQ). These include how one corrects for adsorbed and absorbed vapors from the experiment, and how one applies distributions in volatility from literature in order to calculate the effects of partitioning on the pollutant phase distribution. Due to the complexity and enormity of these databases/models and the limited reporting from many of the studies that inform these systems, a comprehensive evaluation of these uncertainties is difficult.

We bridge the gaps between emissions inventories and models by reviewing the most important sources for direct organic particle emissions in the U.S. We then apply the updated emissions scale factors directly in CMAQ and assess their impact on policy analyses. Finally, we recommend revisions to the inventories and emissions models so that transport models best reproduce the emission magnitudes and trends that have been constrained by focused lab/field studies.

Long-Term Assessment of Sunset OC/EC with Chemical Speciation Network Measurements. STEVEN G. BROWN, Elizabeth Landis, Hilary Minor, Theresa O'Brien, Joann Rice, *Sonoma Technology, Inc*

As part of a U.S. Environmental Protection Agency (EPA) project to evaluate the feasibility of the Sunset Semi-Continuous Organic and Elemental Carbon (OC/EC) monitor, EPA sponsored the deployment of this monitor by local air quality agencies in Chicago, Illinois; Houston, Texas; Las Vegas, Nevada; St. Louis, Missouri; Rubidoux, California; and Washington, D.C. Sunset monitors were collocated with existing 24-hr measurements of OC and EC made via filter sampling as part of the EPA's Chemical Speciation Network (CSN); at Houston, St. Louis, and Washington, they were also collocated with Aethalometer instruments, which measure black carbon (BC). Sunset data were compared to CSN and Aethalometer data to assess whether the Sunset monitors could be deployed in a routine monitoring network application in lieu of instruments that make filter measurements. Agencies encountered significant operational issues with the Sunset monitors, substantially reducing the number of valid data points for the multi-year deployment. After screening for these issues, and excluding results that were suspect, we found that Sunset OC generally compared well with the CSN OC (r2=0.73 across five sites); the Sunset/CSN OC ratio was on average 1.06, with a range among sites of 0.96 to 1.12. Sunset thermal EC and CSN thermal EC did not compare as well, with an overall r2 of 0.22, possibly because 26% of the hourly measurements were below the Sunset EC detection limit. Sunset Optical EC had a much better correlation to CSN thermal EC (r2=0.67 across all sites), with an average Sunset/CSN EC ratio of 0.90 (range of 0.7 to 1.08). There was also a high correlation of Sunset Optical EC with Aethalometer BC (r2=0.77 across all sites), though with a larger bias (average Sunset/Aethalometer ratio of 0.56). There was no systematic difference among the measurements by site location, i.e., Sunset Optical EC was consistently lower than Aethalometer BC at all three sites, with no significant seasonal variation. Collocated Sunset instruments at St. Louis had high precision, with r2 values of 0.93 for OC and 0.91 for Optical EC. Somewhat surprisingly, the diurnal pattern of OC was fairly invariant, while a morning peak was observed for EC at all sites. Overall, operational issues with the Sunset monitors were persistent at all sites, but when the instruments were operating well, collected data were comparable to results from the CSN and the collocated Aethalometers.

4CA.34

Effects of Sugarcane Pre-Harvest Burning on Aerosol Optical Properties in the Cauca Valley, Colombia. ANGELA VARGAS, Jennifer Marin, Lady Mateus, Nestor Rojas, Rodrigo Jimenez, German Ruega, *Universidad Nacional de Colombia*

Open biomass burning increases the concentration of gaseous pollutants such as CH4, CO, SO2, NOX, VOCs, and Particulate Matter (PM), which contains trace metals, organic compounds, elemental carbon and ions. Pre-harvest burning in extensive sugarcane plantations is a significant source of elemental carbon and organic compounds, including highly carcinogenic and mutagenic polycyclic aromatic hydrocarbons (PAHs), which can be transported to urban centers.

Palmira, a city with 350,000 inhabitants in the Cauca river Valley, is surrounded by 238,204 Ha of sugarcane plantations and is the center of sugarcane–related agroindustrial activity. Health data show that its population suffers different diseases commonly related with air pollution, such as ischemic heart diseases (17%), cerebrovascular diseases (8%), chronic respiratory diseases (7%) and acute respiratory diseases (5%). Furthermore, the impact of pre-harvest burning emissions on local air pollution in Palmira has not been determined.

This work focuses on the analysis of physical and optical properties of aerosols in Palmira with the aim to estimate the impact of sugarcane pre-harvest burning on air quality. The sampling site is located at the National University of Colombia (3º30’44.2620” N, 76º,18’27.3960 W) on a building rooftop. A sun photometer CE-318 of AERONET network was used to measure long term the Aerosol Optical Depth (AOD) and Angstrom Exponent, furthermore a Nephelometer IN 101 of SPARTAN network to measure Total and Back scattering (Red, Green and Blue).

AOD values oscillated between 0.01 and 0.42, higher than AOD measured at large cities in Colombia. The Angstrom Exponent was 1.54, associated with fine particles. The aerosol size distribution shows two size modes, a fine mode around 100 nm and a coarse mode around 3 um. The preliminary data of sun photometer and nephelometer show relationship between AOD (500 nm) and Total scattering.

Measuring the Physical Properties of Refractory Black Carbon off the Los Angeles Coast. JOSEPH KO, Trevor Krasowsky, George Ban-Weiss, *University of Southern California*

Black carbon (BC) is widely known to impact the radiative balance of the atmosphere, subsequently playing a role in global climate. The physical properties of refractory black carbon (rBC) were measured using a single particle soot photometer (SP2) on Catalina Island between September 7 and September 14, 2017. Catalina Island is located off the coast of Southern California, approximately 22 miles southwest of the Port of Los Angeles. The mass concentration, number concentration, and coating thickness was analyzed in conjunction with local/regional meteorology to characterize rBC properties for different meteorological regimes in this semi-remote sampling location. The campaign-averaged mass and number concentrations were 0.04 µg/m^3 and 20 cm^{-3}, respectively. This is approximately an order of magnitude lower than what has been observed in recent studies for the Los Angeles basin. Using the leading-edge-only technique, we found that approximately 27% (±19%) of rBC particles were thickly-coated, which is close to the lower end of values from past aircraft measurements in Los Angeles and the upper end of previous ground measurements in Los Angeles. HYSPLIT back-trajectory analyses were used for approximate source characterization. Many large fires in the Pacific Northwest were coincidentally active during the time of the sampling campaign, and preliminary back-trajectories show a high probability of impact from these biomass-burning events. The potential for spikes in rBC measurements due to passing cargo ships is also assessed.

Evaluating Inter-seasonal Urban Environment-mixed Black Carbon-induced Radiative Effects over Eastern India.

SHUBHA VERMA, Shantanu Pani, Sanhita Ghosh, Sauvik Santra, *Indian Institute of Technology Kharagpur*

The abundance of absorbing aerosols during the pre-monsoon season, consisting of locally emitted black carbon (BC) and of dust transported from near-by and far-off region have been suggested leading to elevated atmospheric heating effect. Sensitivity experiments using state of the art aerosol-chemistry-climate models reveal impacts of prevalent absorbing aerosols during the pre-monsoon season on the monsoon precipitation over India. Since atmospheric BC concentrations peak close to major source regions thus giving rise to regional hot-spots, BC-induced radiative warming effect could be more significant on a local to regional scale than the global, which in turn can have strong implications for the regional hydrological cycle. It is difficult to quantify such effects at a finer resolution of the urban scale using large-scale chemistry-climate models due to their coarser resolution and inefficiency to simulate fine scale aerosol properties.

Long-term observations of BC aerosols encompassing all seasons in an urban atmosphere in eastern India provided a unique opportunity to quantify the inter-seasonal urban environment-mixed BC-induced radiative effects. Under an influence of inter-seasonal transport processes and season-specific anthropogenic activity, urban environment-mixed BC-induced radiative effects were evaluated in the vicinity of aerosol composition constituted of enhanced anthropogenic constituents during winter/northeast monsoon season and elevated dust storms during summer/southwest monsoon season. In the present study, we applied a receptor modelling approach to quantify these effects. This was done through the application of long-term simultaneous observations of BC in conjunction with the total aerosol concentration and aerosol optical properties in the configuration of aerosol optical and radiative transfer model. Modelling experiments were designed using this model to simulate urban environment-mixed BC-induced radiative effects.

Our study indicated while the surface BC concentration exhibited a large seasonal variability, the value of BC-AOD was consistently high throughout; except during southwest monsoon season when this value was lower by about three times than that during rest of the seasons. A considerable change in the net radiation balance and an enhancement in radiative forcing efficiency and the atmospheric heating rate was estimated when BC was mixed with atmospheric aerosol constituents compared to unmixed BC; seasonal mean radiative forcing efficiency values due to mixed BC was about 8 to 13 times the unmixed BC value at the top-of-atmosphere. The urban environment-mixed BC-induced radiative heating effect during summer was estimated being higher than during southwest monsoon by 13% only, compared to by a factor of two times during winter season. While the summertime mean value of radiative forcing efficiency was about two times, the southwest monsoon mean value of the same was five to seven times the value during winter at all layers of the atmosphere. Enhanced urban environment-mixed BC-induced net radiative warming effect inferred during summer and southwest monsoon season was found consistent with our postulate about the possible signatures of this estimated effect in real observations of seasonal surface temperature features. Our study thus suggests mitigation of BC emissions may not be sufficient to curb urban environment-mixed BC-induced warming effect under the prevalence of prominent dust transport; thus drawing attention towards the complex role of mitigation measures to reduce pollution-induced radiative effects and its impact on regional climate.

Engineering Controls to Reduce Exposure to Respirable Crystalline Silica during Stone Countertop Grinding.

CHAOLONG QI, Alan Echt, *NIOSH*

Natural and engineered stone countertops became increasingly popular among consumers in recent years. Unfortunately, a large amount of dust that contains crystalline silica can be produced during stone countertop fabrication and installation. Inhalation of respirable crystalline silica (RCS) is one of the best-documented workplace hazards, with a large body of research strongly demonstrating that chronic overexposures cause silicosis and increase the risk of lung cancer. Finishing stone countertops using handheld grinders was among the tasks with the highest exposures to RCS documented in a NIOSH Health Hazard Evaluation at a stone countertop factory, where the exposure levels exceeded the NIOSH Recommended Exposure Limit (REL), even during wet grinding with water supplied to the grinder. In this study, NIOSH researchers investigated two additional engineering control measures for reducing workers' exposures to RCS during stone countertop grinding: a mobile dust control booth where countertop grinding was done inside the booth, and a sheet-water wetting method in addition to the existing water-fed grinder. The effectiveness of these two engineering control measures was evaluated in a series of field surveys and the results are reported in this presentation.

4CM.3

Microwave-Assisted Catalytic Total Oxidation of Methyl Ethyl Ketone over Co3O4 Catalyst. QUI NGUYEN VAN, Ha Than Quoc An, Thanh Nguyen Dinh, *Institute of Applied Materials Science - VAST*

Methyl ethyl ketone (MEK) is commonly used as a solvent in several chemical processes, but now emissions of MEK to the atmosphere can lead to human health and wider environmental problems. A combination process of catalytic oxidation and microwave heating was employed to remove MEK over Co3O4 nanostructure catalyst. The results showed that MEK has been decomposed effectively at 325 ^{0}C. Compared to conventional heating, the microwave assisted catalytic reaction was enhanced by lowering the operation temperature and has had no decrease in the catalytic activity when the space velocity increased from 11000 to 22400 h^{-1}. The results reveal the advantage of microwave energy for the reaction. Co_3O_4 catalyst showed a high endurance against water vapor in stream of the reaction.

4CM.4

Effect of RH Change on Pressure Drop of Loaded Cellulose Filter Media with Hygroscopic Deposits.

CHENXING PEI, Qisheng Ou, David Y. H. Pui, *University of Minnesota*

Current air filter test methods load test filter with non-hygroscopic blends, primarily dust, thus the testing RH is not a big concern. However, hygroscopic particles, mainly salts, are important portion of the ambient air pollutant. It is worthwhile to study the hygroscopic particle loading properties of air intake filters. Our previous research found that the loading RH has an impact on the test filter holding capacities when the hygroscopic particles were loaded. However, those research loaded the test filter media at the constant RH, which is not real in applications. The RH may change rapidly in some scenarios, such as thunderstorms in hot summer would increase the RH from a certain percentage to 100%. For the loaded filter media, this kind of RH change would not only affect how pressure drop increases during the high RH period, but also have impact on the loaded hygroscopic deposits. In this study, we studied the impact of RH change on the loaded hygroscopic deposits. We used potassium chloride, ammonium sulfate, ammonium nitrate to load the test filter media separately. We first loaded the test filter media to 4 inch of water at X% RH, and stopped the atomizer while keeping the test filter face velocity constant. Then we changed the RH to Y% and stopped the test until the instantaneous pressure drop change rate was less than 0.1inch water/hr. The pressure drop was recorded during the test. The selected X% and Y% RH covers from below the salts' efflorescence RH to above their deliquescence RH, thus salts may experience the transition from dry state to wet state or the reverse transition. The final pressures were compared as a function of the X%, Y% RH and salt kinds.

Enhancing the Efficiency of Flat-plate Electrostatic Precipitator by a Diffusion Charge Method. Chih-Te Wang, Chang-Chin Chou, Yu-Chau Wang, Shui-Jen Chen, Ken-Hui Chang, WEN-YINN LIN, *Institute of Environmental Engineering and Management, NTUT*

Diffusion charging is one of the commonly used collection methods for electrostatic trapping of nano-particles (dp<100 nm). Diffusion charging can avoid the direct contact between charging electrode and volatile organic compound (VOC) in treating the waste air. Research has shown that diffusion charging is a practicable method, but there is little experimental evidence for the maximum value of charged particles after charging. Therefore, this research designed a diffusion charger and let the air flow though the charger to generate high concentration ions for particle charging. The factors that can influence particle charging contain ion concentration, particle diameter, and charging time. This research investigated the charge distribution of different particle diameter at various carry gas rate and voltage of diffusion charger. Finally, charged particles stream into flat-plate Electrostatic precipitator to investigate particle penetration at different carry gas rate and voltage. The experimental results indicated that particle charging efficiency, increased with increasing air flow rate and corona voltage of unipolar diffusion charger, The best charging efficiency occur when the corona voltage and air flow rate is 3.3 kV and 3 lpm, respectively. Moreover, 50 nm particle carries 3 elementary charge with ratio of 36.7%, and 100 nm particle carries 6 elementary charge with ratio of 38.9%. Moreover, particle penetration decreased with increasing airflow rate and corona voltage of unipolar diffusion charger, and penetration of nanoparticle was higher than that of submicron-particle (100 nm <dp<1000 nm). Because, the surface area of nanoparticles is too small, it is hard for nanoparticles to get enough charge, and be collected. Therefore, there are a larger proportion of nanoparticles can pass through the flat-plate Electrostatic precipitator, compared with submicron-particles. The diffusion charging method is a feasible method was carried out through an indication of effectiveness of the experimental result. It is adopted both removal of organic waste gas and environment that must avoid the risk of explosion.

4CM.6

Charge and Filtration Characteristics of Novel Porous Fibers. Chih-Te Wang, Shao-Tai Lee, Jia-Hong Wang, Shi Jia-Xi, Chih-Chieh Chen, WEN-YINN LIN, *Institute of Environmental Engineering and Management, NTUT*

Filtration is one of the common, economical and effective methods for removing particulate. The electrets of surface in the fiber can achieve low-pressure loss without affecting the efficiency of filtration due to their electrostatic attraction. Previous researches were pointed out that increasing the specific surface area of fiber can increase the charge. At the same time, there were studies that had porous or hollow properties of the fiber can increase the specific surface area. In this study, three kind fibers of smooth, hollow porous and notch porous were prepared by electrostatic spinning. Then, with the charge test, the three fibers were charged by corona discharge method. The results showed that the average surface voltages were -0.82 kV (smooth), -0.90 kV (hollow porous) and -1.10 kV (notch porous), respectively. The highest charge of the porous fiber is due to its high surface area. Besides, experiments on the filtration efficiency of three types of fibers were carried out. Among them, the decrease rate of the perforated fiber penetration rate of the notch porous was more remarkable than that of the smooth and hollow porous fiber. After charging, the average fiber efficiency of smooth fibers increased from 0.16 to 0.29, the hollow porous fiber increased from 0.20 to 0.39, and the groove porous fiber increased from 0.21 to 0.47. The results showed that the charging and filtration quality of the notch porous fibers were better than the smooth and hollow porous fibers. Excellent performances will allow for notch hollow fibers to be easily integrated in the future various industries.

4CM.7

A Novel Technique for Testing Filter Media Using Monodisperse Aerosol as a Function of Aerodynamic Diameter.

Simon Payne, Martin Irwin, Tyler J. Johnson, JONATHAN SYMONDS, *Cambustion*

The standard ISO29463:2011 method of testing filter media efficiency as a function of particle size uses a Differential Mobility Analyzer (DMA) to select particles by electrical mobility. Depending on the size range of the source aerosol, it is possible for larger particles than selected to pass through the DMA, due to multiple-charging induced by the particle charging process used prior to classification. This can affect filter efficiency measurements if not taken into account. In addition, most DMAs are size limited to less than 1 micron.

The Aerodynamic Aerosol Classifier (AAC, Tavakoli and Olfert, 2013) is an instrument which classifies particles by aerodynamic diameter instead of electrical mobility diameter. Because it does not require particles to be electrically charged, this mitigates the DMA multiple-charging artefacts previously described. Furthermore, the currently available version of the AAC can classify particles from 25 nm to over 6 µm. This paper explores substituting an AAC for the DMA usually used in ISO29463:2011 filter efficiency tests to mitigate the issues described above.

Samples of filter media from two different types of half-mask respirators were mounted in an in-line filter holder. In turn, both sodium chloride and dioctyl sebacate aerosol sources from a nebuliser were classified using an AAC, to provide a monodisperse aerodynamic size selected aerosol. The penetration efficiency of the filter media in response to the monodisperse aerosol was evaluated by comparing particle number concentrations measurements upstream and downstream of the filter media using a condensation particle counter (CPC). This process was repeated over an aerodynamic size range from 50 nm to 3 µm (the upper limit was limited by the maximum detectable particle size of the CPC). As a comparison, the AAC was replaced with a DMA, to conform with the method prescribed by ISO29463:2011 (although only up to 750 nm due to the size limitation of the DMA).

On equivalent diameter size axes, the penetration efficiency curves between the AAC and DMA methods are similar, except for classification sizes smaller than the peak size of the nebulised source aerosol. This difference is attributed to a significant number of the particles selected by the DMA having 2 or more charges, and thus being much larger than intended. Due to the fact that a large proportion of particles remain uncharged in a neutraliser, the transmission efficiency of the AAC was found to be 1.5 to 5.5 times higher than the neutraliser-DMA system. This high transmission efficiency could be useful for more exotic test aerosols available only in limited concentrations.

Improving the Accuracy of PM2.5 Sampling with Chilled Teflon Filter. Krishna Kumar Shukla, Sneha Gautum, Te-Hsien Hsieh, Ziyi Li, Pei-Yun Shih, THI-CUC LE, Chuen-Jinn Tsai, *National Chiao Tung University, Taiwan*

Most of the ambient aerosol sampling and monitoring devices use filter media to capture particles (such as $PM_{2.5}$) after the size-selective pre-separators (such as well impactor ninety-six (WINS), or very sharp cut cyclone (VSCC)). Smart heaters are further used to condition the inlet aerosol temperature to avoid water vapor condensation in the aerosol monitors. Previous studies from our group (Liu et al., 2014) showed that the aerosol evaporation loss was occurred which reduced the aerosol mass concentration. An increment in the deviation was also observed with decreasing loaded particle mass and increasing ambient or conditioning temperature (Liu et al., 2015). The aim of the present study is to use a chilled filter sampler in which the aerosol stream before the filter holder was chilled to 4 ^{0}C after the aerosol was dried to a relative humidity (RH) of 24.5 ± 5.1% to improve the accuracy of $PM_{2.5}$ sampling. The observed test results from the chilled filter sampler showed that the evaporation loss of volatile species was effectively suppressed. However, the gravimetric weights of chilled filter samples were slightly heavier than the normal filter samples, which were quantified by using hydrophobic test particles, due to slight increase in the remained water content in the former. A thin layer of condensed water coated on the sampling particles was the key to reduce the evaporation loss. After correcting the mass concentration of $PM_{2.5}$ for the excess remained water content, the accuracy of $PM_{2.5}$ sampling was greatly improved with the average positive bias reduced substantially from 15.2% to 2.6% for $PM_{2.5}$ ranging from 10.6 to 44.5 $\mu g/m^3$.

Keywords: aerosol sampling, evaporation loss, aerosol conditioning, $PM_{2.5}$ sampling inlet, aerosol instrumentation

Improvement of Monitoring of Radioactive Aerosols of Ground-Level Air near Chernobyl NPP. ALEXANDR KALYNOVSKYI, Victor Krasnov, Boris Ogorodnikov, *Institute NSP NPP, Ukraine*

In order to control a work safety in areas erection of new safe confinement "ARKA" construction and staff's location near Chernobyl NPP (ChNPP) the radioactive aerosols (RA) of ground-level air were monitored. Sampling of aerosols was carried out by pumping air through filters FPP-15-1.5 which had area about 0.8 m^2. Average filtration rate was 8 - 12 000 m^3/day. The consist and activity of radionuclides in aerosols was determined by gamma spectrometer (CANBERRA). The concentration of ^{137}Cs was varied within $1.1 \cdot 10^{-4}$ - $2.3 \cdot 10^{-1}$ Bq/m^3, ^{154}Eu - $2.8 \cdot 10^{-7}$ - $1.4 \cdot 10^{-3}$ Bq/m^3, ^{241}Am - $1.6 \cdot 10^{-6}$ - $1.3 \cdot 10^{-2}$ Bq/m^3. The specific content of dust varied in range $3.2 \cdot 10^{-3}$ - $1.6 \cdot 10^{-1}$ mg/m^3.

Researches of collecting aerosols using filter compositions from fibrous materials was carried out to improve informational data and reliability of monitoring. This researches included.

1. Laboratory studies of filter properties of composite materials are fulfilled at increased linear air flow rate (80 and 160 cm/s), where, first layer (prefilter) was coarse-fiber FPP-70-0.3, PET-100-0.02 and FPS-110-0.2, second - thin-fiber FPP-15-1.5. By analysis results of experiments data was revealed possibility of qualitative estimation of aerosol dispersion and were obtained mathematical models of filter resistance growth due to dust accumulation, which helped to determine that composition FPS-110-0.2 and FPP-15-1.2 is optimal.

2. Real sampling of aerosols by two-layer filters was performed on a regular air sampling system of near ChNPP. The natural ^{7}Be, ^{210}Pb and ^{212}Pb were markers of submicron aerosols. Based on studies results carried out qualitative assessment of aerosol dispersion, which showed that radionuclides of Chernobyl's genesis of ^{137}Cs, ^{154}Eu, ^{241}Am were mainly on aerosols with AMAD more than 1 µm.

Analysis studies results showed that, firstly, aerosols distribution over the composite filter's layers depends on type of fibrous material of first layer and weather conditions during sampling of air. Secondly, prefilter assumes main dust load during intensive construction, erection works and earthworks. As FPP-15-1.5 filter is clogged more slowly with dust and that increased a lifetime of sampling system.

Using the filters composition in observing passage of radioactive cloud from the accident Fukushima-1 NPP in Ukraine from March 24 to May 16, 2011 allowed us to say that ^{134}Cs and ^{131}I were in air on submicron particles.

4CM.11

Reductions of PAH and Nitro-PAH Emissions from Diesel Engine by Using Micro-Emulsified Diesel-based Hydrous Glycerol Fuels.

SHENG-LUN LIN, Yen-Yi Lee, Fang-Ching Lee, Wen-Jhy Lee, *Cheng Shiu University, Taiwan*

Cleaner power generation technology is one of the way to deal with the major environmental problems, such as air pollution, human health, and global warming, coming with the uses of traditional fossil fuels. The major energy resources could be varied significantly depended on different country, and lead to several constraints on their greener energy development. For example, the electricity-powered vehicle could be a very “low emission” technique in the country that generate the power from “greener” processes (wind, solar, and hydraulic utilities). However, those techniques are technically hardly to be achieved in the country, who lacks those resources, such as Taiwan. Alternatively, the refuse-derived fuel became more important in a populated densely country. If the wastes of one manufacturer could be systematic transferred to energy resources of other producers, the manufacturing and waste treatment cost, pollutant and carbon emission, and health risk of the local residents might be effectively reduced by our local manufacturers. Therefore, the global economy impact to a local industry could be simultaneously reduced by this buffering system. This study focuses on the energy transformation techniques from wasted hydrous glycerol of the biofuel production processes to a diesel engine fuel. Glycerol was added into diesel by the fractions of 5–20 wt.% with the specific amount of surfactant additions. A homogenizer with 15,000 rpm was employed to emulsify the diesel blend by 5 min, and followed by an 750-kW ultrasonic homogenizer. A 90-day standing and the size distribution of glycerol droplets in diesel were done after the fuel preparation for ensuring they were well-mixed and thermodynamic stable. Furthermore, deionic water was added into pure glycerol by 20% to simulate the biodiesel-produced glycerol composition. Therefore, the stable blends, including G1, G5, G10, G15, and G20 (glyceral, G), were prepared as pure-glycerol-diesel fuels, while HG1, HG5, HG10, HG15, and HG20 (hydrous glycerol, HG) were hydrous glycerol-diesel blends. A 4-stroke, single-cylinder diesel engine generator (5 kW) with an output power control-measurement system, was employed to test the target fuels. The engine speed was controlled at “A” level, which is defined by European Stationary Cycle (ESC) as nlo + 0.25(n_{hi} - n_{lo}). Three loads, including 25, 50, and 75% of maximum engine load, were then tested. The emissions of PM, CO, and HC were monitored by a portable monitoring device (E8500, E Instrument.), while 16 PAHs and 6 *nitro*-PAHs were collected in particulate and gaseous phases separately by a stoichiometric sampling system. A GC/MS and a LC/MS-MS system were utilized to quantify PAHs and nitro-PAHs, respectively. Results shows that the brake specific fuel consumption (BSFC) were increase along with the increasing glycerol additions to the maximum 9.2%, while the heating value of G20 was 11.8% lower than that of pure diesel. The combustion enhancement of OH· provided by glycerol could partially balance the heating value effect. Additionally, the PM, CO, HC, particulate/gaseous PAHs, total PAHs, total BaP_{eq}, and total *nitro*-PAHs concentrations were all reduced significantly. These finding could also be resulted from that the oxygenated fuel have more fuel-containing O and was pyrolyzed to from more O· to easily initiate the combustion reaction. Also, lower volatility could also induce the low temperature combustion to prevent the soot formation. However, the NOx emission increased by glycerol addition, which is the major concern of the modern diesel engine. The better and more completely combustion of fuel provide higher heat release rate and temperature in the cylinder and increase the NOx level in the exhaust. Interestingly, the HG addition further reduce the NOx emission with, when the other pollutants were still inhibited. The optimal fuel based on pollutant emission concern is HG10, reporting an effective use of the waste biproduct from the biofuel production processes. Furthermore, the completely circular economically energy production could be achieved while the feedstocks (alcohol and fatty acid) of biofuel could be replace by refuse of waste material.

Preparation of Non-Woven PTFE Fibers Using Electrospinning. HAN-BIN KIM, Ki Bong Lee, Myong-Hwa Lee, *Korea Institute of Industrial Technology, Korea University*

Bag house system is commonly used to remove particulate matters in exhaust gases from various combustion facilities. Bag filter is the most important component to determine the performance of a bag house system. Bag filter made of PTFE polymer is widely used to collect particulate matters in dust-laden flue gas, due to its strong chemical resistance, low surface free energy. Especially, PTFE laminated membrane filter, which an expanded PTFE film is laminated on a woven glass fiber filter, is generally used in a bag house system because nonwoven PTFE bag filter is quite expensive. However, the filter has extremely low air permeability, which resulted in low filtration performance due to high pressure drop. PTFE foam coated filter, which has a high air permeability, was developed in our research group. However, the filtration efficiencies of the filter for fine particles are not high enough at initial stage of filtration, since the pore size of the filter is larger than 10 um1).

A new method was proposed to improve the performance of the PTFE foam coated filter in this study. The PTFE nanofibers fabricated by electrospinning were coated on a PTFE foam coated filter to decrease the pore size and improve the collection efficiencies for fine particles.

Investigation of Charge Decay Degree in Electret Filters with Various Surface Charge Densities. WOO JIN LEE, Jungho Hwang, Myong-Hwa Lee, *Korea Institute of Industrial Technology, Yonsei University*

PM2.5, i.e. particulate matters less than 2.5µm, is one of the major components that cause serious impact to a human respiratory system. Recently, many people utilize an air respirator and an air purifier to protect their body from fine particles. Electret filter, which is made by meltblowing a polypropylene polymer followed by corona charging, is generally used as a filter medium. However there are several reports that particle collection efficiency of the filter decreases over time by exposure to organic species and water(Motyl et al., 2006; Xiao et al., 2014). Many researchers tried to clarify the charge decay mechanism, however, it is still uncertain.

We investigated the charge decay degree in electret filters with various surface charge densities. As a result, we found that electret filter with higher surface charge density was more tolerable to isopropyl alcohol exposure than others.

Regeneration Characteristics of Filter Bag Cartridges with Various Pleating Geometries. JIN SIK KIM, Myong-Hwa Lee, *Korea Institute of Industrial Technology*

Pleated filter cartridge is a good alternative to treat a large amount of dust-laden gas in a limited space for a dust collector, because it has larger filtration area than a cylindrical filter bag. In general, the filter cleaning efficiency of a pleated filter bag is less than that of a cylindrical one and highly dependent upon pleat geometries, despite of its advantage. So far, the optimal pleating method of the filter media was not suggested yet. Dimensionless parameter, α, which is the ratio of pleat height to pleat width, is introduced to investigate the regeneration characteristics of a pleated filter cartridge in this study.

Six pleated filter bags with different pleat geometries (α=1.07, 1.36, 1.65, 1.93, 2.21, 2.50) and a cylindrical filter bag were prepared and tested in a lab-scale pulse-jet bag house system. The filter functioning antistatic water repellency was used as a filter medium and fly ash particles were introduced as the test particles. In addition, the filtration velocity was set to 1 m/min which is the usual filtration velocity in a real plant and the air flowrate maintained uniformly to have a constant filtration velocity by using a pitot tube and an inverter. Filter regeneration was conducted at the maximum allowable pressure drop of 100 mmH_2O under the clean-on-demand mode. The results showed that there was an optimum pleat geometry based on the filter cleaning characteristics of pleated filter cartridges, which had a maximum filtration area and reasonable filter cleaning efficiency.

Conversion of Sulfur Dioxide and Nitrogen Oxides to Particulate Matter. MYONG-HWA LEE, Woo Jin Lee, Han-Bin Kim, Jin Sik Kim, *Korea Institute of Industrial Technology*

Sulfur dioxide, nitrogen oxides as well as particulate matters are coexisted in flue gas. Flue gas desulfurization for sulfur dioxide and selective catalytic reduction for nitrogen oxides, are usual control technologies. However, the equipment are too expensive to apply to a small-scale combustor. A new approach which converts them to particulate matter, was challenged in this study. The resultant species can be easily removed in a bag house system.
Sulfur dioxide concentration decreased drastically by injection of ammonia at the temperature of 200ºC. At the same time, drastic increase in particle number concentration was observed through the SMPS(Scanning Mobility Particle Sizer) measurement. However, there was no change in nitrogen monoxide concentration, even if the same amount of ammonia for SO_2 removal was injected in flue gas. Therefore, the effect of further oxidation of nitrogen monoxide to nitrogen dioxide on particle formation was also investigated. The characteristics of gas to particle conversion will be discussed in this study.

Filtration Performance of Electret Filter Composed of Nano/Micron Fibers. TOSHIKI MURAKAMI, Takafumi Seto, Yoshio Otani, *Kanazawa University*

Air filters composed of electrostatically charged fibers (electret filters) are commonly used for respirators. In the present work, mixed nanofiber/microfiber electret filters were investigated in term of the filter quality factor. The mixed nano/microfiber electret filters were prepared by an electrospinning process. From the scanning electron micrographs of prepared filters, it was found that both nanofiber and microfiber were well mixed to form uniform packing structure. The average fiber diameter of nanofibers was 200 to 1200 nm depending on the spinning condition, while that of microfiber was controlled to be 1800 nm.

The filtration performance of filters was investigated by measuring the collection efficiency, E (=1-P, where P is the penetration) and the pressure drop. Test NaCl particles were generated by an evaporation-condensation method and they were classified by the differential mobility analyzer (DMA) into the monodispersed particles of 30 to 300 nm in the electrical mobility diameter. The number concentrations of DMA-classified aerosol at the inlet and outlet were measured by a condensation particle counter (CPC). The penetration through the electret was measured with and without electrical neutralization by soaking it with isopropanol. The filtration velocity was varied from 1 to 10 cm s^{-1}.

The filtration performance of charged and neutralized filters was evaluated by the filter quality factor, q_f, defined as the ratio of logarithm of particle penetration to the pressure drop: $q_f = -\ln P/\Delta P$, where, ΔP, is the pressure drop across the filter media. As the nanofiber diameter becomes smaller, q_f of charged filters increased and reached over 0.25 at the nanofiber diameter of 600 nm, however, q_f decreased when the fiber diameter was smaller than 600 nm. The total charge on the filter was estimated by comparing the collection efficiencies with/without neutralization. Q of the 600-nm fiber was estimated to be more than of 4×10^{-4} Cm^{-2} but it decreased with decreasing the fiber diameter.

Filtration performance of the electret was also analyzed by the single fiber filtration theory by taking into account the bimodal distribution of fibers. The filtration performance of the mixed fiber filter after neutralization was in good agreement with those predicted by introducing the inhomogeneous factor calculated from the bimodal distribution of fibers. As the fiber diameter decreases, q_f of neutralized filter increased as predicted.

Fine Particle Emission from Power Plants and Their Contribution to Air Quality in Korea. SUNGNAM CHUN, Suji Kang, Gayoung Lee, *Korea Electric Power Corporation Research Institute, Korea*

Now a day, the fine particle problem has become the most important air pollution issue in Korea. We occasionally experience the occurrence of high concentration events of particulate matter in the air that exceed the air quality standards during the spring season, and the Korean government is pushing various strict policies to reduce the emission of particulate matter. The goal of the Korean government is to low the fine particle concentration in the air by 30% in 2022 comparing with that of 2017. In Korea, the particulate matter is known to be contributed by the inflow of foreign countries and various domestic emission sources. Also it is considered that the contribution of power plants on fine particle concentration in Korea are approximately 4 % based on the 1st fine particles that are emitted as fine particles directly from stack and increase to 15 % including the second fine particles that are emitted as gaseous phase when these leave stack but converted to fine particles in the air through chemical reactions. Even though Korean government is trying to convert the energy portfolio from fossil to renewal energy era, until now more than 30 % of the electricity comes from fossil fuel sources, such as coal, oil and gas. Most of the fossil fuel used to make electricity is coal in Korea and demand of fine particle emission reduction is increasing.

This paper has summarized the assessment results of particulate emissions from Korean coal-burning power plant. We measured fine particle concentration in flue gas was measured using USEPA 201A and ISO 23210. We also measured the filterable particulate matter(FPM) and condensable particulate matter(FPM) and analyzed the chemical composition of particulate matter. The fraction of fine particulate matter to total particulate matter was assessed in coal-burning power plants. In addition, we reported the operating status of pollution control facilities, such as SCR, ESP, and FGD in a flue gas system from a boiler to a stack to assess the fine particle concentrations at each facilities and their fine particle removal efficiency.

To assess the contribution of power plants to the fine particulate matter concentration in the air, the background concentration monitoring station was constructed and we compared the concentration data obtained at the station with the measurement data obtained near the power plant. The fine particulate specimens which was collected at the back ground monitoring site and near the power plants were analyzed to assess chemical composition and we developed to assess the emission source apportionment.

In order to improve the air quality especially fine particulate matter concentration in Korea by reducing particulate matter emissions from various sources, it is necessary to identify the target sources and understand their emission characteristics. And it is also necessary to apply appropriate control technology to the emission sources. The data presented in this paper are considered to provide important information in establishing a control strategy for power plants as a large scale emission source to mitigate the fine particulate matter emission.

A Study on Pulverized Coal Combustion Using a Two-Stage Flat-Flame Burner with a Transition from a Reducing to Oxidizing Environment. Adewale Adeosun, DISHANT KHATRI, Zhiwei Yang, Richard Axelbaum, *Washington University in St. Louis*

Coal particles experience a transition from a reducing to oxidizing environment in the near-burner region of pulverized coal (pc) burners. For the first time, we report a fundamental study of ignition of a coal-particle stream experiencing a flame environment that transitions from a reducing to an oxidizing environment (termed reducing-to-oxidizing transition). High-speed videography is used to observe the particles in situ, and scanning electron microscopy is used to characterize the sampled particles. The effects of particle size on ignition are presented for four size bins (63-74 µm, 75-89 µm, 90-124 µm and 125-149 µm) for PRB subbituminous coal at two nominal gas temperatures (1300 K and 1800 K). The results show that the ignition modes under reducing-to-oxidizing conditions are different from those in purely oxidizing conditions, especially for small particles in a 1300 K gas temperature. The hetero-homogeneous ignition mode is dominant at the higher gas temperature, except for the 125-149 µm particle size range, where homogeneous-to-heterogeneous ignition occurs. For an 1800 K gas temperature, ignition delay time is relatively independent of particle size under either oxidizing or reducing-to-oxidizing conditions. However, the reducing-to-oxidizing transition increases ignition delay time by, on average, 100% over those of oxidizing conditions. At a gas temperature of 1300 K, ignition delay time depends strongly on particle size. For large particles (i.e., 90-124 µm and 125-149 µm), there exists a crossover at which the ignition delay times under reducing-to-oxidizing conditions are less than those under oxidizing conditions.

4DU.4

Nanostructure as a Paradigm for Describing Carbon Structure and Interpreting Its Formation. RANDY VANDER WAL, Madhu Singh, Joseph Abrahamson, Chethan Gaddam, Kuen Yehliu, Chung-Hsuan Huang, *Penn State University*

Combustion produced soot is highly variable with details as dependent upon Nanostructure – structure on the nanoscale has always existed. Yet recognition of its importance in governing carbon's chemical reactivity is comparatively recent. Nanostructure is generally described by the parameters of lamellae length, curvature (or tortuosity) and separation distance, measured perpendicular to the graphene segments. High resolution microscopy is necessary to access these scales with image analysis algorithms used to extract the spatial metrics. Aided by automated processing codes, distributions of each metric can be accumulated for their statistical description. Since 2004, nanostructure as a subject has appeared in more than two dozen papers. These studies have addressed nanostructure a) characterization, b) impact upon (carbon) oxidation, c) dependence upon molecular precursor and d) dependence upon combustion (i.e. formation) conditions, along with other related studies. Algorithms for nanostructure quantification provide measures by which to gauge the impact of these different formation conditions. Since the variations and more broadly formation conditions are generally specific to the source, nanostructure can serve as a paradigm by which to differentiate combustion sources by their combustion environments.

4DU.5

Towards Establishing a Semi-Empirical Soot Formation Model for Strained, Non-Premixed, Oxygen-Enriched Flames.

PHILLIP R. JOHNSON, Rajan K. Chakrabarty, Benjamin M. Kumfer, *Washington University in St. Louis*

The emission of carbonaceous soot particles to the atmosphere affects both the environment and human health. The presence of soot in industrial combustion systems also plays an important role for radiation heat transfer. For these reasons, prediction of soot fraction is often desirable in simulations of industrial boilers, furnaces and kilns using computational fluid dynamics (CFD). The complexity and size of these systems, in addition to limits on computational resources, often necessitates the use of reduced combustion models and simplified soot formation models. Many of the existing soot models are semi-empirical in nature and do not require large reaction mechanisms for fuel combustion because they are dependent only on the concentration of acetylene or the parent fuel. Existing models generally fall into two categories: one-step models in which total soot formation rate is calculated from a single Arrhenius expression, and two-step models in which nascent soot particle nucleation and surface growth are treated separately. However, most were developed for a specific application and/or validated under fuel-air combustion conditions only; their use in a different context, such as oxy-combustion, can lead to inaccurate predictions.

As reported in the literature, a soot-producing flame can become non-sooting (blue) with the combination of oxygen enrichment and fuel dilution, even while maintaining constant flame temperature. In addition, soot-producing flames may become blue with increasing strain rate. In this study, the accuracy of recognized and commonly used semi-empirical soot models is evaluated in response to oxygen enrichment and variable strain rate. The models are tested in a series of laminar counterflow flames which span the sooting-to-non-sooting transition. Flames are modeled using CHEMKIN with detailed fuel combustion chemistry. The gas-phase results are post-processed to calculate profiles of soot formation rate and volume fraction. Results indicate that existing models tend to overpredict soot formation in highly-strained flames and upon increasing oxygen enrichment, and do not adequately capture the sooting-to-non-sooting transition.

A new one-step semi-empirical soot formation model is proposed that aims to be applicable in a wide variety of flames. This model considers the effects due to changes in flame structure, caused by fuel dilution and oxygen enrichment, and also strain rate, on the soot formation rate. The model predictions are compared against experimental data from the literature for validation. Results demonstrate markedly improved accuracy for non-premixed, oxygen-enriched flames.

4DU.7

Submicron Ash Formation in Advanced Pressurized Combustion System.

DISHANT KHATRI, Zhiwei Wang, Akshay Gopan, Adewale Adeosun, Richard Axelbaum, *Washington University in St. Louis*

The novel Staged Pressurized Oxy-Combustion (SPOC) process, can reduce the efficiency penalty for carbon capture in coal-fired power plants by over half. The SPOC process incorporates a unique boiler configuration to enable combustion of pulverized coal at elevated pressure (15 bar) with low flue gas recycle. Although a promising technology for power generation, the impact on pollutants, such as the particulate matter (ash) has not yet been established. Therefore, in this work, the formation and evolution of sub-micron particles will be evaluated in a newly constructed 100-kWth pressurized oxy-combustor. The particle size distribution (PSD) of the sub-micron particles, and their morphology and composition will be measured using SMPS and SEM/EDX, respectively. Measurements will be carried out to study parametrically the factors which can affect submicron formation at the high pressure and high-temperature conditions. Parameters that can affect ash formation includes pressure, gas composition, and residence time. First, the effect of oxygen concentration (gas composition) at distance of 10 inches from burner tip, and 15 bar pressure will be studied to separate the effects of gas composition from those of residence time and pressure. To observe the effect of pressure, the pressure will be varied from 3 to 15 bar for a 30% oxygen concentration and at a distance of 10 inches from burner tip. Finally, to observe the effect of residence time, the particles will be sampled at 4 different axial locations keeping gas input composition at 30% oxygen molar concentration and a pressure of 15 bar. The experimental data, along with analytical models will help to understand the observed trends during these studies.

4DU.8

Employing Laser Pyrolysis to Generate Carbon Onion Particles and Its Application to Proton Exchange Membrane Fuel Cell.

JE HYEON YEON, Indae Choi, Sei Jin Park, Mansoo Choi, *Seoul National University, Seoul, Korea*

Various carbon nano-materials, such as graphene, carbon nanotubes and carbon black, have been used as supports for the catalyst particles in Proton exchange membrane fuel cells (PEMFCs) on account of conductivity and low cost. Due to the extremely high cost of widely employed pt catalyst particles in PEMFCs, it is desirable to load these particles on a robust support material such that the degradation of the support does not render the noble metal useless. Among the various forms of carbon, carbon nano-onions (CNOs) draw particular attention due to their concentric shells with high degree of graphitization. CNOs can be continuously synthesized by laser pyrolysis of hydrocarbon source (such as acetylyene and ethylene), and therefore has the advantage over other forms of carbon nano-materials due to the scalability of the production method[1].

Here, we present a CO2 laser induced pyrolysis of gaseous hydrocarbons to produce CNOs, and explore the parameter space toward the goal of producing CNOs over other carbon particles (such as amorphous soot). We demonstrate that the size, morphology and the number of graphitic shells are easily controlled by adjusting the experimental parameters. Owing to the high degree of graphitization, the CNOs show enhanced durability against oxidative potentials to commonly used commercial carbon materials such as Vulcan XC-72. Platinum-decorated CNOs have been used to fabricate PEMFCs and they are shown to have comparable performance to conventional cells, and the accelerated stress test reveals that the durability of the cells improved.

Incorporating Engineering Context into General Chemistry Laboratory for a more Contextually Relevant and Engaging Experience for Engineering Students. CHANG YU WU, Kent Crippen, Lorelie Imperial, Corey Payne, Korolev Maria, Philip Brucat, *University of Florida*

The laboratory environment can offer valuable first-person, hands-on experiences that complement and extend the process of learning from other parts of a course. To this end, we are developing a unique laboratory curriculum for general chemistry for undergraduate engineers that more deeply engage students in authentic science and engineering practice. Our project involves a series of Design Challenges, which are problem-based laboratory activities based upon the NAE Grand Challenges for Engineering. These Design Challenges situate chemistry concepts and skills in an authentic engineering context with supports for the engineering design process. For engineering majors, contextualizing the learning of chemistry in such a way is theorized to strengthen the connection between the domain knowledge of chemistry and its application in everyday work, which enhances interest, efficacy, learning as well as retention. The user-centered design process enables us to keep our focus on the involvement of our target audience in all stages of development.

We will present our design framework, how results from usability testing are used to illustrate our iterative evidence-based development process. We will then present results of an initial pilot study from across one semester of student use (covering Grand Challenges topics of Restore and Improve Urban Infrastructure, Providing Universal Access to Clean Water, Making Solar Energy Economical, and Develop Carbon Sequestration Methods). For usability, data sources include video-recorded observations, field notes, student artifacts. For the pilot study, the assessed outcomes include chemistry content knowledge, self-efficacy, metacognition, and motivational variables. Both qualitative and quantitative analyses are used to address the research questions. The preliminary results showed positive changes in participant satisfaction, feeling like an engineer and for learning how to collaborate. Plans for additional re-design of the model and further study will be discussed.

4ED.2

NGDE: A Simple, MATLAB-based Code for Solving the General Dynamic Equation. JAMES CORSON, George Mulholland, Michael Zachariah, *University of Maryland*

The general dynamic equation governing aerosol particle nucleation, coagulation, and surface growth [1] is taught as part of undergraduate- and graduate-level college courses. This complicated integro-differential equation can only be solved analytically for a small number of special cases, so one must resort to numerical methods to solve the GDE. Unfortunately, the methods used to solve the equation often obscure the underlying physics: for example, moment methods (see e.g. [2]) transform the integro-differential equation into integrals that must be solved numerically for the various moments of the aerosol size distribution, while sectional methods [3-4] require assumptions about the size distribution within each bin. These considerations complicate efforts to understand the physics represented by the GDE.

To address these concerns, Prakash et al. [5] developed a code to solve the GDE using a nodal method, where aerosol particles exist only at discrete size nodes. This method is similar to the sectional method but obviates the need to consider intra-bin processes. Instead, the NGDE code uses a simple size-splitting algorithm – essentially, linear interpolation – to deal with particles that form or grow to sizes between two nodes. The original NGDE code was written in C; recently, we have converted the code to MATLAB. As part of the conversion, we have added several features to improve its function as a teaching tool, including implementation of a dynamic time-step algorithm that improves code stability and speeds up the calculation by orders of magnitude, and a post-processing tool that shows the evolution of the aerosol size distribution with time. We have also imbedded the Bohren Mie Code [6] in the post processing tool to show the evolution of the optical cross sections for the aerosol. Furthermore, because MATLAB is widely used in science and engineering curricula, users can more easily make changes to the code to add additional features or to implement different physics models for the constituent dynamic processes (e.g. substituting a different nucleation model in place of classical homogeneous nucleation theory with the self-consistent correction).

We will demonstrate the features of the NGDE code using sample problems including coagulation of an initially monodisperse aerosol, pure surface growth, and the full GDE for condensation of aluminum vapor. We will also discuss lessons-learned from including the NGDE code as part of an Aerosol Dynamics course at the University of Maryland.

Aerosol Education with Community Citizens in Brandywine. AKUA ASA-AWUKU, *University of Maryland*

Here we describe an educational project launched with a community group in Brandywine Maryland (BTB Coalition), the University of Maryland, College Park and the AGU thriving earth Exchange to educate and inform local citizens of air quality and particulate matter concerns in the southern Maryland region. Successful community science requires skills and approaches that are not often emphasized or rewarded in traditional science research or education. This presentation will discuss the strategies, challenges, and outcomes to engage aerosol scientists with local communities in aerosol and air quality educational issues.

4ED.4

Image Analysis on Particle Size Distribution and Particle Tracking by Python-programming. CHIH-HSIANG CHIEN, Huanhuan Jiang, Wyndham Hudson, Bing Guo, Chang Yu Wu, Myoseon Jang, Paul Gader, *University of Florida*

The high-resolution camera has become popular and affordable in recent years. Image analysis from the camera can be processed by Python programming, which is not only reliable and efficient but also accessible for newcomers. In addition, Python has great libraries to support image analysis for free. Our laboratory has developed Python-based codes to analyze particle size distribution and to track particle motion on surface. We have applied the technique to an electrodynamic shield (EDS) system to understand the particle removal mechanism of EDS. Particle motion on soiling surface under a dynamic electric field was monitored by a microscope integrated with a digital high-speed camera. To determine the particle size distribution, each particle in an image was labeled and its area was determined by the number of pixels it covered. Frequency distribution was then calculated for size distribution. To obtain the particle trajectories, a three-step program was developed: 1) locate Gaussian-like blobs with a specified size in an image, 2) identify the same particle in different image frames, and 3) link the positions for a particle in each frame to generate a particle trajectory. The feasibility of these two programs was confirmed by inputting standard images with known particle size distribution and trajectories. The results showed the developed programs can successfully distinguish particles from images with varied geometry and generate particle trajectories. These two programs can serve as powerful tools for study of particle motion in air or on a surface.

Fundamentals of Air Pollution Engineering: A Free Online Resource for Aerosol Education. RICHARD FLAGAN, John Seinfeld, *California Institute of Technology*

The book Fundamentals of Air Pollution Engineering, 1988, is textbook that is available online in entirety for free. According to Amazon.com, it is "A rigorous and thorough analysis of the production of air pollutants and their control, this text for engineering students focuses on the formation and control of pollutants in combustion processes. The authors introduce the concept of air pollution engineering, providing an in-depth treatment of combustion, the formation of particulate matter and other pollutants, the principles of aerosol behavior, and basic theories of the removal of particulate and gaseous pollutants from effluent streams. In conclusion, they provide a framework for an optimal air pollution control plan. Suitable for advanced undergraduate and graduate courses in chemical, civil, environmental, and mechanical engineering, this volume assumes a basic familiarity with thermodynamics, fluid mechanics, and heat transfer. Supplements include new appendices, abundant worked-out examples and end-of-chapter problems, and a solutions manual, available from the authors upon request."

4ED.6

Combining Transferable Skills and Aerosol Science in Education. ANTTI LAURI, Taina Ruuskanen, Laura Riuttanen, Hanna Vehkamäki, *University of Helsinki*

We studied students' learning of transferable skills during a two-week research-intensive course. Advanced analysis of atmospheric aerosol and aerosol-related data was the topical emphasis on the course. The students were working on real data, and the project work they carried out during the course was a real research problem.

The transferable skills whose learning we studied were data analysis skills, academic writing skills, oral presentation skills, learning and teaching skills, and project and time management skills. All of these skills were included in the expected learning outcomes of the course. We invited the 30 students on the course to answer on a survey in the beginning of the course in order to find out about their expectations about learning transferable skills on the course. In the end of the course they answered on a second survey. The aim of the second survey was to find out how much they learnt during the course, and whether their learning on the course fulfilled their expectations.

The students on the course represented a rather mixed audience. Their stages varied between undergraduate students and postdoctoral researchers. The majority of the course participants were doctoral students. They also represented different disciplines: physics, meteorology, atmospheric science, Earth science, and biology.

We found that overall, the students felt they did learn the transferable skills included in the expected learning outcomes. The students found mixed groups in terms of stage of studies and discipline appreciated rather than problematic. Even more importantly, working with real data and research problems was considered motivating and rewarding.

Low-cost Particulate Matter Sensors: Developing, Piloting and Disseminating Appropriate Educational Resources to Support Community Use. Stefania Squizzato, Katrina Smith Korfmacher, Cait Fallone, Kathleen Gray, Dana Haine, John Prochaska, Diana Hernandez, Peggy Shephard, PHILIP K. HOPKE, *University of Rochester Medical Center*

A wide array of low-cost air quality sensors are available and have created opportunities for individuals and communities to monitor their exposure to a range of air pollutants (e.g., particulate matter, ozone). These sensors hold great promise for: enhancing environmental health literacy to promote behavior change that reduces exposure to air pollutants; enabling communities to investigate and document local sources of air pollution; and, supporting air quality focused citizen science and other environmental science education initiatives. However, users may not understand the resource requirements of various sensors, best practices for using the sensors to monitor their local environment, data uncertainties, and appropriate interpretation of results. This gap in knowledge may undermine effective use by individuals and communities. For example, users may mistakenly compare indoor air quality measurements and take action based on the recommendations outlined in the EPA's Air Quality Index (AQI) which only addresses outdoor air quality. Or users may overestimate the accuracy of sensor data, leading to frustration and mistrust when experts or agencies do not act on their findings. Better understanding of the potential and limitations of these sensors will help individuals and communities effectively use this new technology to better inform and promote actions that are protective of public health.

Low-cost air quality sensors have been used by citizen science, environmental justice and other non-governmental community groups to identify local sources of particulate matter and local patterns of ambient air pollution to inform public health action. Within the low-cost air quality sensor market, users are confronted with a range of sensors, each with different needs for and ability to access electricity, secure physical sites, Wi-Fi connectivity for downloading, etc. Similarly, in selecting a sensor, users may have different needs pertaining to pollutant(s) of interest, data accuracy, units, or reporting. Simply identifying the most accurate monitor, successfully capturing data, and providing platforms to share data with others does not adequately support community environmental health goals. Potential users need to understand the limitations of the technology (and resulting uncertainty) and the resource requirements of various sensors. They also need to know how to interpret their findings, especially in the context of the AQI.

The project presented here represents a collaboration between three National Institute of Environmental Health Sciences (NIEHS) Environmental Health Science Core Centers (University of Rochester, University of North Carolina-Chapel Hill and University of Texas Medical Branch) and their community partners (WEACT). The goal of the project presented here is to enhance users' understanding of air pollution and available sensor technologies in order to enable them to effectively choose, use and interpret sensor data in order to meaningfully address their community's public health concerns in three states (New York, North Carolina and Texas).

Specifically, this goal will be accomplished through (i) developing educational materials tailored to a community audience; (ii) evaluating the effectiveness of these educational materials by piloting them in four diverse communities and (iii) disseminating these materials through the NIEHS Partnerships for Environmental Public Health Network, along with other citizen science and environmental science education networks.

These educational materials will improve community stakeholders' capacity to select, deploy, understand and communicate the results of low-cost particulate matter monitors. By increasing community users' understanding of sensor technology, sources of uncertainty and how to interpret the results, our project will not only enhance the ability of communities to investigate and document local sources of air pollution but will also provide them with the resources to help them evaluate whether or not sensor use is appropriate in the context of their air quality concerns.

4ED.8

A Software to Map the Time-lapse History of Global Air Pollutions (TH-GAPs). MAOHUA PAN, Zechen Yu, Chang Yu Wu, Myoseon Jang, Paul Gader, *University of Florida*

Air pollutions, such as particulate matter (PM), NOx, Ozone, SO2, in heavily polluted areas can pose significant health effects to human beings. Time-lapse history of these air pollutants' concentration could help student better learn the global air quality patterns, while visualization of these data could also impress the public. Our lab has designed a software (TH-GAPs) to process data downloaded from Goddard Earth Sciences Data and Information Services Center (GES DISC) to generate a series of time-lapse videos for visualizing the dynamic behavior of global air pollutants. MatLab APP Designer is used to create the software. The observation or simulation data (e.g. ground level ozone concentration) are loaded into the software and then averaged according to the selected average time interval (e.g. 2 month) and/or the selected resolution (e.g. 1°x1°). Afterwards, these processed data could be saved and transferred to the second part of TH-GAPs to generate maps of the time-lapse concentration history of different air pollutants. Total ozone and ground level PM2.5 data from 2010-2016 were used to prove the feasibility of this software. Videos of the time-lapse ground level PM2.5 and total ozone concentration over South Pole, North Pole and around the world were successfully generated, and maps generated from this software are identical with maps from the National Aeronautics and Space Administration (NASA). Compared with commercially available software, the TH-GAPs is fast, convenient, open source and easy to share, and there are no strict requirements for the resolutions of the input data. This implies that Matlab App Designer can be used for software design to make air quality data processes faster and convenient, and to make air pollution results more illustrative and acceptable to the public. Our work demonstrates incorporating programming into environmental engineering can create better tools to engage people to care more about environmental problems.

4IA.1

Quantication of the Impact of Cooking Processes on Indoor and Outdoor, Primary and Secondary Organic Aerosols and Volatile Organic Species. IMAD EL HADDAD, Felix Klein, Andre S.H. Prévôt, Urs Baltensperger, *Paul Scherrer Institute*

Cooking is expected to be an important source of particulate pollution in indoor and outdoor environments. We conducted more than 100 individual experiments to characterize the particulate and non methane organic gas emissions from various cooking processes, their reaction rates and their secondary organic aerosol yields. We used these emission data to develop a box model, for simulating the cooking emission concentrations in a typical European home and the indoor gas-phase reactions leading to secondary organic aerosol production. We demonstrate that cooking dominates the particulate and gas phase air pollution in non-smoking European households. The gas-phase concentrations consist of about 60%, 20%, 10%, 9%, and 1% of small aldehydes, unsaturated aldehydes, larger aldehydes, acrolein, and terpenes, respectively. While frying processes are the main driver of the aldehyde emissions, terpenes are mostly emitted due to the use of condiments. Compared to primary aerosol emissions, which are dominated by frying processes, secondary aerosol production is negligible in indoor environments. In addition to providing an assessment of the impact of different cooking processes on indoor air, we will present a comprehensive framework for identifying the main parameters controlling indoor gas and particle phase concentrations. Based on the same emission data, we will also discuss the influence of cooking for outdoor air.

4IA.2

Three-Stage Modelling of Indoor Aerosol Formation Caused by Reaction of Ozone with Volatile Organic Compounds Emitted from Air Fresheners. Thai Phuong Vu, SEUNG-BOK LEE, Gwi-Nam Bae, *HoChiMinh University of Natural Resources and Environment*

A three-stage modelling of aerosol formation potential (AFP) was proposed to investigate secondary organic aerosols caused by ozone reaction of volatile organic compounds emitted from air fresheners. The AFP was defined as a function of formed aerosol mass per unit ozone reacted. The experimental system consisted of a reaction chamber, ozone and pure air generators and ozone and particle monitoring instruments. The volume of the cube-shaped reaction chamber made of 2-mil (about 51 µm) FEP Teflon film was 1 m^3 (1× 1× 1 m). The chamber was installed in a wooden box equipped with a door in order to avoid any light disturbances from the outside. The ozone concentration was monitored every one minute using a U.V. photometric O_3 analyzer (TEI 49i). The particle number size distribution was determined using a scanning mobility particle sizer (SMPS), which consisted of an electrostatic classifier (TSI 3081) and a condensation particle counter (CPC, TSI 3010). Total particle number concentration was also monitored using an ultrafine condensation particle counter (UCPC, TSI 3025) with a 1-sec response time. The air temperature and relative humidity in the Teflon chamber were maintained at 20^oC and 20%, respectively. The total sampling flow rate for monitoring particles and ozone in the chamber was controlled to be similar to the flow rate of ozone injected into the chamber. A 0.5-mL test specimen of a liquid-type air freshener was contained in a 50-mL glass petri dish with a diameter of 65 mm that was then placed in the bottom of the chamber. Ozone injection started after the test specimen was set and occurred into the center of the chamber through the top surface using a photometric O_3 calibrator (API 401). The ozone calibrator was operated at three different concentrations (50, 100 and 200 ppb) at a flow rate of 4.0 L/min. Each experiment lasted for 4 h. The aerosol formation process can be classified into three stages. The first stage of the AFP was determined at beginning time t_0 ($t_0 = 0$) to time t1 at which particle was not formed, $AFP_0 = 0$. The second stage of the AFP began from t1 to time t_2. There was a nucleation burst and conversion of formed particles to larger particles (size of 100 nm), $AFP_1 = a_1\Delta O_3 – b1$ ($a_1 = 0.4 – 1.9$ and $b_1 = 0.6 – 4.3$). The third stage of the AFP began from t2 to end experiment time t_3. There was stable increase in particle concentration, $AFP_2 = a_2\Delta O_3 – b_2$ ($a_1 = 0.7 – 3.0$ and $b_2 = 15.0 – 27.0$). Values of ai and bi were depended on concentration and quantity of biogenic volatile organic compounds in the air fresheners and ΔO_3 was ozone quantity reacted. The three-stage modeling was easy to be applied for investigation of the secondary organic aerosol formation under other environmental conditions such as ozone concentration, temperature, air freshener quantity, and initial volatile organic compounds. The three-stage modelling was easily and effectively used to evaluate and control secondary aerosol sources for indoor pollution management.

4IA.3

Impact of Household Daily Activities on Indoor Air Quality. Estela Vicente, Fernanda Oduber, Carlos Blanco-Alegre, Ana Isabel Calvo, Amaya Castro, Roberto Fraile, Teresa Nunes, CÉLIA ALVES, *University of Aveiro*

Household activities, such as cooking and cleaning, are known to generate considerable amounts of particulate matter indoors. In this study, the impact of four standard vacuum cleaners (washable filter bagless vacuum, wet vacuum, bag vacuum and a HEPA filter equipped robot) and two flat irons (steam iron and a steam iron with boiler) on indoor particulate matter levels was studied. The measurements were performed in León (Spain), in a house living room trying to reproduce the everyday conditions in late autumn (all the doors and windows were kept closed due to the cold weather outside - situation 1). Additionally, the particulate levels generated during steam ironing were also characterized while keeping the room doors opened and the windows closed (situation 2). On average, 45 min measurements were conducted during vacuum cleaning and 3 and half hours during ironing. After each household activity, the sampling continued until the restoration of particle concentration to the original level. Background indoor air measurements were also performed. A real-time laser photometric instrument (TSI, DustTrak DRX 8533) was used to record particulate matter concentration over time. Submicrometer particle number concentrations were measured using a Scanning Mobility Particle Sizer (SMPS, TSI Incorporated), which gives real time size distributions and number concentrations in the range from 7.64 to 310.6 nm. Simultaneous sampling with a PM_{10} high volume air MCV (model CAV-A/mb) instrument for gravimetric quantification was carried out. The equipment was operated at a flow of 30 m^3/h. Particulate samples were collected on pre-weighed 150 mm quartz fibre filters (Pallflex®) for gravimetric and chemical analyses. The gravimetric quantification was performed with a microbalance (XPE105 DeltaRange®, Mettler Toledo). After gravimetric determinations, thermo-optical analysis of PM_{10} filters was performed to obtain the carbonaceous content.

Regarding vacuum cleaning, the highest increase of PM_{10} concentrations and total particle number concentration was observed using the wet vacuum, 14.5 fold and more than 40-fold compared to background concentration, respectively. A 2-fold increase in PM_{10} mass over the background level was observed during the use of the HEPA filter equipped robot. $PM_{2.5}$ to PM_{10} ratios ranged from 0.43 (HEPA filter equipped robot) to 0.81 (wet vacuum). As regards the total number of particles, the readings were in the same order of magnitude, before, during and after the vacuum operation. Total carbon accounted from 9.0 ± 1.8 (wet vacuum) to 45.5 ± 4.1 (HEPA filter equipped robot) % wt. of the PM_{10} mass.

Average PM_{10} mass concentration in situation 1while steam ironing, without (191 ± 16 µg/m^3) and with boiler (180 ± 20 µg/m^3), increased more than 15 and 14 times compared to background concentration, respectively. Steam ironing under situation 2 conditions still increased the PM_{10} concentration 4.8 times (60 ± 17 µg/m^3). The lowest $PM_{2.5}/PM_{10}$ ratio (0.87) was observed during steam ironing under situation 2 conditions. Total particle number concentrations were from one to almost two orders of magnitude higher during ironing than prior to the start of the activity. Total carbon accounted for 30.4 ± 5.1 (steam ironing, situation 1), 51.8 ± 8.2 (steam ironing, situation 2) and 38.8 ± 3.1 (boiler steam ironing, situation 1) % wt. of the PM_{10} mass.

4IA.4

Reduction of Fine Particle Exposure for Bedrooms in Home According to Operating Conditions of an Air Purifier.

JUNHO JI, Gwang-Jae Lee, *EcoPictures Co., Ltd.*

Human indoor activities generate airborne fine particles which contribute to the increase of indoor fine particle concentration at home. Ultrafine particles are emitted during some activities e.g. burning candle or incense, cooking, spray use, computer printing and household cleaning (Gehin et al., 2008). Recently, interest in fine particles has been increasing in Korea. This makes it difficult to ventilate in house when fine particle concentration in outdoor air is high. Portable air purifiers are widely used at home. However, a portable air purifier at home does not seem to be used properly. The purpose of this study is to clarify the relationship between the reduction of particulate exposure and the operating condition of the air purifier, that is, the air flow rate. This gives very useful information for the consumer using portable air purifiers. At the same time, carbon dioxide was measured to propose a ventilation cycle in the family bedroom. We expect to reduce the public's anxiety against fine particles by supplying the field quantitative data. This study was conducted on the bedrooms of a small new apartment. The volume of each bedroom was 18.8, 22.8 and 24.84m3, respectively, and the test was conducted in an empty rooms. Area coverage of test air purifier was 29 square meter. An optical particle counter (OPC, portable aerosol spectrometer, model 1.109, Grimm, Germany) was used to monitor particle size distribution within the range 0.25–32 μm. An indoor air quality (IAQ) monitor (NDIR CO2 Detector, model IQ-610xtra, GrayWolf Sensing Solutions, USA) was used to measure the CO2 concentration in the range from 0 to 10,000 ppm. First, we measured the characteristics of natural decay of PM10, PM2.5, and PM1. The initial particle size distribution affected to the reduction of particle concentrations. The larger the particle, the greater the concentration decrease due to gravity. Continuous operation of an air purifier reduces indoor fine particles. Over time, relatively large particles were removed quickly and concentrations of PM10, PM2.5 and PM1.0 were similar. The results show that as the operation air flow rate of the air purifier decreases, the Clean Air Delivery Rate (CADR), which represents the performance of the air purifier, is lowered. Compared with the maximum airflow condition of the air purifier, CADR in the low air flow rate was reduced by about one third. Under the maximum air flow rate, the amount of fine particle exposure decreased to 10% when compared with the initial fine particle concentration and to 40% at the low air flow rate condition. When there was one person in a 24.84 cubic meter room, the carbon dioxide concentration increased to 1290 ppm for 30 minutes. The amount of fine particle exposure decreased to 20% and 60%, respectively for the operation conditions of maximum and low air flow rates. However, when there were two people in a room, the concentration of carbon dioxide in the room rose to 1250ppm for 30 minutes and 1970 ppm for an hour. In future research, we will propose the operating time of the air purifier considering the ventilation cycle which can effectively reduce the fine particle exposure in the indoor bedroom and the living room.

4IA.5

Carbonaceous Particles and Gaseous Compounds in Kitchens and Outdoor Air of Different Homes. CÉLIA ALVES, Ana Rita Oliveira, Teresa Nunes, Estela Vicente, Susana Marta Almeida, Mário Cerqueira, *University of Aveiro*

We spend most of our time in indoor environments. As building infrastructures are increasingly air tight to save energy, epidemiologic studies need to understand the extent to which outdoor levels of air pollutants remain a determinant of exposure and, therefore, of health in the indoor environment. Many of the outdoor pollutants are also some of the most common contributors to unhealthy air inside homes, due in part to a ubiquitous and possibly surprising activity: cooking. Moreover, kitchens started to become living spaces and, in most cases, are the hubs of the home.

A monitoring program involving 4 kitchens with different characteristics and the respective outdoor air was conducted in the region of Aveiro, Portugal, in October and November 2017. Low volume samplers were used to collect particulate matter ($PM_{2.5}$) onto quartz filters, which were subsequently analyzed for their carbonaceous content (organic and elemental carbon, OC and EC) by a thermo-optical technique. Passive sampling of volatile organic compounds (VOCs) and carbonyls was also carried out.

Indoor and outdoor formaldehyde concentrations were 7.61±3.08 and 1.49±0.67 $\mu g/m^3$, respectively, whilst the corresponding acetaldehyde levels were 7.94±4.63 and 0.41±0.36 $\mu g/m^3$. Formaldehyde never exceeded the protection threshold of 100 $\mu g/m^3$ imposed by the Portuguese legislation. The mean indoor VOC levels ranged as follows ($\mu g/m^3$): benzene 0.92-2.9; ethylbenzene 0.80-1.7; toluene 3.9-9.3; m+p-xylene 2.4-5.8; o-xylene 1.0-2.2; styrene 0.27-1.5; 1,4-dichlorobenzene <0.10-1.2; trichloroethylene 0.35-2.5; tetrachloroethylene <0.10, and α-pinene 0.15-13.6. In general, all the kitchens except one registered indoor-to-outdoor VOC concentration ratios lower than one. The indoor levels of benzene, trichloroethylene, toluene, styrene and tetrachloroethylene were well below the thresholds laid down by the national regulations (5, 25, 250, 260 and 250 $\mu g/m^3$, respectively). Xylenes, toluene and styrene were highly correlated with each other, both indoors and outdoors, suggesting common emission sources.

The mean indoor $PM_{2.5}$ concentrations ranged from 13.8 $\mu g/m^3$, in the kitchen located in a rural area, to 30.2 $\mu g/m^3$ in a city center apartment with permanent occupancy. A mean outdoor level of 18.3 $\mu g/m^3$ was obtained in the rural area, while very close mean values were recorded in the center and outskirts of the city (27.6-29.5 $\mu g/m^3$). Total carbon (TC = OC + EC) accounted for about 30% of the $PM_{2.5}$ mass in the kitchens of the rural area and city center apartment. In the kitchens of houses with less central location, but near roads with intense traffic, the $TC/PM_{2.5}$ values were around 40%. The corresponding outdoor mass fractions ranged, in general, between 20 and 40%, the highest values being registered at the two locations more influenced by traffic. In general, the indoor OC/EC ratios were higher than the corresponding outdoor values. Regardless of location, ratios higher than 2 were usually observed. The highest OC/EC ratios were measured at the beginning of the sampling campaign, when the region was hit by wildfires.

4IA.6

Aerosol Reduction Capability of an Air Purifier in the Real Living Room Environment. CHANG GYU WOO, Hak-Joon Kim, Yong-Jin Kim, Bangwoo Han, *Korea Institute of Machinery and Materials*

The concern to indoor air quality increased as people understand relation of air quality and health. According to a report, the market size will increase to $ 23.8 Billion by 2020. Many performance test methods including AHAM AC-1-2015 were developed, however, the performance test results are not directly translated to the environment of customers' houses. Air cleaning performance can be different because of air leakage, outdoor air quality, operation modes of air purifiers, and so on. An air purifier was deployed in a 36.8 m^2 living room of a house which is in Daejeon, Republic of Korea. Clean Air Delivery Rate (CADR) was calculated by varying experimental conditions with all doors were closed. KCl particles were used as test particles and were generated by using six-jet atomizer. The initial concentration of test particles in the living room was not critical to CADR values. Due to the air leakage of the house, outdoor $PM_{2.5}$ concentration showed negative relationship with CADR value. 10~30 $\mu g/m^3$ of $PM_{2.5}$ values were suggested as experimental range from the annual average of $PM_{2.5}$ concentration in major cities in Korea and from the CADR measurements in this work. This research can contribute to preparation of test method of air purifier in the real environment as well as understanding of air purifier operation in the real environment. This research was supported by National Strategic Project through the National Research Foundation of Korea (NRF) funded by Ministry of Science and ICT(NRF-2017M3D8A1091919).

Linking PM2.5 Indoor Air Quality and Emission Factors Measured during a Cookstove Intervention Trial in Rural India.

MOHAMMAD MAKSIMUL ISLAM, Roshan Wathore, Grishma Jain, Karthik Sethuraman, Hisham Zerriffi, Julian Marshall, Rob Bailis, Andrew Grieshop, *North Carolina State University*

Combustion of biomass in residential cookstoves is a major source of household air pollution (HAP), an acknowledged threat to human health. Although there are many studies showing the effect of biomass cookstove on HAP, there are limited number of studies where both emission and indoor air quality were measured across different seasons and at different locations. Thus, the quantitative linkage between cookstove emission and indoor air quality is still poorly constrained. In this study, we assess the effect of a cookstove intervention trial on indoor PM2.5 concentration as well as its seasonality and inter-site variability in two rural areas in India (Kullu in Himanchal Pradesh; Koppal in Karnataka). This study also aims to improve our ability to quantify the link between cookstove emissions and indoor PM2.5.

The study had three ~3-month-long measurement periods (baseline, follow-up-1, follow-up-2) for each location. Indoor PM2.5 concentrations were measured during ~5000 cooking events of traditional and alternate biomass and modern-fuel stoves. Measurements were conducted with real time mobile instruments (RTI micro-PEMS) which include a nephelometer and collect filter samples for gravimetric PM2.5 analysis. For a subset of those cooking events, simultaneous emission measurements were conducted by a portable instrument (STEMS). Kitchen performance tests (KPT) were performed to assess daily household fuel use. Use of stoves was measured using temperature-logging stove use monitors (SUMs) installed on all cooking appliances.

Preliminary data analysis for baseline showed that median indoor 24 hour average PM2.5 concentration in households in Kullu having Himansu Tandoor (improved chimney heating stove) as primary stove was 72 μg/m³, approximately a factor of two lower than for those with Traditional Tandoor stoves (142 μg/m³). A similar trend was observed during follow-up-1 (267 and 138 μg/m³ for Traditional and Himansu Tandoor respectively), indicating reduced pollution was associated with improved chimney stoves. Indoor PM2.5 for both stoves during follow-up-1 were twice as high as baseline, consistent with strong seasonality in PM2.5 concentrations. The households in Kullu and Koppal having LPG (either as primary or secondary stove) had median PM2.5 concentrations of 91 and 111 μg/m³ respectively, about 1.5-2 times less than households having no LPG stoves (142 and 207 μg/m³ in Kullu and Koppal respectively). The median PM2.5 concentration for houses having primarily traditional stoves was higher for Koppal (206 μg/m³) than Kullu (132 μg/m³), strong evidence of inter-site variability in PM2.5 concentration.

Stove-influenced (SI) periods were identified in the real time PM2.5 data using an algorithm and decay phase of SI periods were used to calculate air exchange rates (AER). Higher AER in Kullu households (11±5 h-1) compared to Koppal (7±4 h-1) may explain the reduced PM2.5 concentration in Kullu for the same stove. Average stove-influenced PM2.5 concentrations were higher during follow-up-1 (1127 and 1045 μg/m³ in Koppal and Kullu, respectively) than non-stove-influenced concentrations (45 and 26 μg/m³ in Koppal and Kullu, respectively). Moreover, stove-influenced PM2.5 concentrations were positively correlated (r2=0.89 & 0.79 for Koppal and r2=0.68 & 0.62 for Kullu during baseline and follow-up-1, respectively) with indoor daily average PM2.5 concentrations, indicating as expected, a strong association between cookstove emissions and indoor PM2.5. PM2.5 emission rate will be calculated using PM2.5 emission factor from emission measurement and fuel consumption rate from KPT. SUMs data will be used to identify cooking events associated with each stove types, and PM2.5 concentrations corresponding to those events will be obtained from SI analysis. Finally, with the help of AER and ventilation characteristics from household surveys, a statistical model will be developed linking emissions rate and indoor PM2.5 air quality.

Investigating Aerosol Emissions from Cooking Oils through a Controlled Chamber Experiment. , Sameer Patel, Itza Beltran, MARINA VANCE, *University of Colorado Boulder*

Cooking is an important contributor to aerosols in home environments. Cooking fumes, especially those produced by heating oils at high temperature can release a large amount of fine and ultrafine aerosols, which may lead to potential long-term hazards to human health. The objective of this study is perform a controlled chamber study to investigate the aerosol emission rates from a variety of popular cooking oils using an electric heat source at a range of smoke points: avocado oil, peanut oil, soybean oil, olive oil, coconut oil, and lard, both with and without the addition of salt, and at a variety of temperatures. Aerosol emissions are characterized in terms of size, volatility, and relative concentrations of black and brown carbon. Aerosol size distributions are characterized using a Scanning Mobility Particle Sizer (TSI) and an Aerodynamic Particle Sizer (TSI). The presence of black carbon and brown carbon will be investigated using an Aethlabs 5-wavelength aethalometer. Finally, aerosol volatility will be investigated using a custom-built thermodenuder. This study will aid in bringing indoor air quality field measurements into perspective by isolating cooking emissions from other potential indoor sources.

4IA.9

Particle Size Distribution of Indoor Aerosols, Natural and Artificial. HYAM KHALAF, Mostafa Mostafa, Mikhail Zhukovsky, *Ural Federal University*

Size distribution of inhalable aerosols is the most significant factor to predict aerosol deposition yield at various respiratory tract locations in human. Recently, electronic cigarette (EC), as the alternative of tobacco cigarette, is increasingly popular all over the world. However emissions from ECs may contribute to both indoor and outdoor air pollution and the number of users is increasing rapidly. In this investigation, mainstream aerosols generated from electronic cigarette were characterized in terms of particle number concentrations and size distributions by using diffusion aerosol spectrometer (DAS). DAS can be assessing in the range from 10-3 µm to 10 µm. Maximum number concentration of injected aerosol particles around 4x104 particles/cm3, most of these particle concentrations within the ultra fine particles (UFP) size range (0 to 0.2 µm) and the other in the size range from 0.3 to 1 µm. With time, the size mode of the particle number is less than 0.2 µm (UFP). The mass and the surface size distributions is presented and compared with bi-modal distribution.

Aerosol Release during Mechanical Solicitation of Tio2 Nano-Additived Paint. CHARLES MOTZKUS, François Gaie-Levrel, Nicolas Feltin, Stephane Delaby, *Scientific and Technical Center for Building (CSTB)*

The market of the nanocomposite materials in the construction industry is exponentially growing. Several types of nano-objects are currently used, in particular titanium dioxide (nano-TiO2). However, many questions are still open concerning the impact of these nanomaterials on the human health and the environment as previous studies showed. The degradations induced by the aging mechanisms could leads to the release of particles into the environment and today the chemical nature, size and concentrations are poorly known. In order to provide new scientific knowledge in this field, a research project called "EMANE" associating the CSTB and the LNE aims to characterize the particle release as a function of various aging scenarios for TiO2 nano-additived paints.

In this study, a nanomaterial called "model paint" was performed in laboratory, composed of an acrylic paint and 5% in mass of nanoparticle of nano-TiO2 (Aeroxide® TiO2 P25 Evonik Degussa). The physicochemical properties were characterized for this "model paint", and also for an acrylic paint and a commercial nano-additive photocatalytic paint. Samples of these three paints applied on the plasterboard plates (10x10 cm²) were submitted to different aging scenarios representative of environmental and use conditions encountered in indoor environments (humidity, temperature, oxidation, cleaning and mechanical solicitation).

The mechanical solicitations of samples were performed by abrasion by a TABER model 5750 linear Abraser. This device has a load arm which moves back-and-forth in a linear manner. The linear movement performed create a mechanical solicitation by friction at the tested material imply a particles released in the aerosol form. Test parameters such as stroke length, speed, load and the abrasive substrate used are adjustable. Two abrasion protocols have been developed. The first (stroke length = 7.6 cm, normal force = 8.3 N, velocity = 60 cycles/s, time = 30 s and cycles number = 30) corresponds to a strong abrasion removing the paint on the plasterboard plates and the second (stroke length = 7.6 cm, Normal force = 3.4 N, velocity= 75 cycles/s, time = 2 min and cycles number = 150) to a moderate with a partial abrasion of the paint. The abrasive substrate used (H18) is made of vitrified clay and has a diameter of 19 mm.

For each type of paint and scenario tested, three tests were carried out for each of the two abrasion protocols, corresponding a total of 165 experiments. In order to study the aerosol release associated with these two abrasion scenarios, the Taber abraser was installed in an experimental chamber to confine the aerosol and to move towards the aerosol emission to sampling isokinetic probes. The aerosols were characterized by real-time measurements (APS, DMS 500 and CNC3007) to measure the number concentration and the size distribution over a size range of 5 nm to 20 µm and by off-line measurements (MEB-EDX) carried out on aerosol samples.

The results obtained by DMS 500 and APS during abrasion on the "model paint" and on the commercial nano-additive paint samples show the emission of aerosols characterized by three particle populations around 60 nm, 200 nm and 2 µm. The results analysis shows the importance to normalize the number of particles emitted to the weight mass losses during an abrasion process for sample comparison. The study provide new scientific knowledge on the behavior of nanomaterials (TiO2 nano-additived paints) and especially on the aerosol released during mechanical solicitation. These new experimental data will allow us in the future to estimate the exposure of the people to manufactured nano-objects.

4IA.12

The Impacts of Cooking on Indoor Air Quality in Passive Houses. Ryan Militello-Hourigan, SHELLY MILLER, *University of Colorado Boulder*

Passive houses are a design concept to reduce energy use in buildings by making the structure tight and extremely insulated. This ongoing study is characterizing the indoor air quality of ten passive houses in Colorado by continuously sampling the air with optical particle counters while performing a repeatable prescribed cooking activity. Measurements are recorded while the occupants are away or minimally active for a period of approximately three hours. During this time, HEPA cleaners are also used to remove indoor ambient particulate matter. After the cleaning period, a hot plate is set up in the kitchen and one egg is fried in one tablespoon (15 ml) of canola oil. All buildings tested in this study feature either continuous or automatic ventilation systems with energy recovery and filtration. For each home, this cooking activity is performed while the homes' ventilation system operates at standard conditions, and then repeated several days later with the homes' ventilation system in "boost" mode for a period of 20-30 min. For the several days in between, a carbon dioxide monitor is also set up in the bedroom to measure daytime and nighttime concentrations. Preliminary results for fine particulate matter (PM2.5) indicate that outdoor particulate levels have little effect on indoor levels, likely due to filtered incoming air and low infiltration rates. PM2.5 levels quickly increase after cooking, but are slow to decay; concentrations generally stayed above the NAAQS 24-hour limit of 35 µg/m3 for over three hours for both ventilation modes. Using boost mode resulted in lower and higher concentrations for different homes, possibly due to variability in egg emissions. These early tests indicate that current ventilation practices may not be adequate for severe cooking events. Preliminary results for bedroom carbon dioxide levels show high variability across the homes with roughly half experiencing uncomfortable levels at night (> 1000 ppm). All ten passive house tests and analyses will be included in the final presentation.

4IA.13

Comparison of Physicochemical Properties and Toxicity of Particles Found Indoors and Outdoors in Occupied Residences – Measurement Methodology.

ANETA WIERZBICKA, Yuliya Omelekhina, Nicklas R. Jacobsen, Anne Thoustrup Saber, Erica Bloom, Patrik Nilsson, Axel C. Eriksson, Joakim Pagels, *Lund University*

Surprisingly little is known about toxicity and physicochemical characteristics of airborne particles found in residences, even though we spend about 65% of our time in homes. Characteristics and toxicity of outdoor particles have been studied and adverse health effects due to exposure have been confirmed. Outdoor particles infiltrate to indoor environments and we are exposed to them indoors but they change their physicochemical characteristics upon infiltration and mix and transform with particles and gas pollutants from indoor sources. Many indoor sources generate particles in amounts that exceed levels observed outdoors by far, for example during cooking or candle burning. There is a need to better understand exposures in homes. The aim of this study was to develop measurement methodology that would allow studying toxicity and physicochemical differences between particles found indoor and outdoor occupied residences.

Week-long measurements were conducted simultaneously indoors and outdoors in sixteen occupied residences in southern Sweden during winter time 2016/17. Residences included in the study were detached single family houses with natural ventilation and apartments with both natural and mechanical ventilation. Occupants kept logbooks of performed activities that were prone to generate particles.

Two identical sets of instruments for indoor and outdoor measurements were used. Instruments were placed in specifically designed enclosures to minimise the noise and disturbance for the occupants. Measurements comprised online assessment of physical characteristics of particles and collection of particles for off-line chemical analysis and toxicological studies in mice. Measured time-resolved physical characteristics were: number concentration and mean size (Nanotracer, 10-300 nm), $PM_{2.5}$ mass concentration (DustTrack DRX), and black carbon concentration (Microaethelometer). Filters from Dustracks DRX were used firstly for gravimetric analysis (corrections for DustTrack readings), then split into three parts and used for the following analysis: policyclic aromatic hydrocarbons quantification (GS-MS), metal analysis (ICP-MS) and ion chromatography. Particles were also collected on a Teflon filter for endotoxin analysis ($PM_{2.5}$ cyclone at flow 15 l/min). $PM_{2.5}$ particles for the toxicological studies were collected using Dekati Gravimetric Impactor (70 l/min).

Particles collected for toxicological studies were extracted and evaporated according to method described by Jalava et al 2005. In short each PTFE sample filter, was extracted twice in 30 ml methanol in ultrasonic water bath for 30 min below 35 degree C. All extracts of particles of one type namely: indoor, outdoor and blanks, were pooled together, sonicated and dried in a vacuum evaporator at 35deg C and 150 mbar.

During the measurement period we collected time-resolved data about physical characteristics of airborne particles indoor and outdoor occupied residences. Average particle number concentration (10-300 nm) was higher indoors than outdoors, and accounted to 6700 cm^{-3} (STD 4700 cm^{-3}) and 2400 cm^{-3} (STD 900 cm^{-3}), respectively. Gravimetrically assessed $PM_{2.5}$ mass concentration was higher outdoors than indoors, average outdoor concentrations were 8.5 μgm^{-3} (STD 6.1 μgm^{-3}) while indoors 4.9 μgm^{-3} (STD 3.7 μgm^{-3}). Extracted mass of particles collected for toxicological studies accounted in total to about 70 mg for indoor and outdoor separately, which was sufficient for conducting toxicological studies in mice, the results are being analysed. Preliminary tests of PAHs, endotoxin and metal analyses confirmed sufficient amounts of particle mass on split filters for the analysis, which are currently ongoing.

Applied measurement methodology proved its suitability for assessment of physicochemical characteristics and toxicity of particles found indoor and outdoor occupied residences. Collected and extracted $PM_{2.5}$ particle mass was also sufficient to perform toxicological studies in mice. These characteristics are needed to increase our understanding of the mixture of particles found indoors, in order to assess health effects and minimize exposure.

Persistence of Wildfire-derived Pollutants in Indoor Environments. LUKAS KOHL, Meng Meng, Joan de Vera, Bridget Bergquist, Colin A. Cooke, Sarah Hustins, Brian Jackson, Arthur W. H. Chan, *University of Toronto*

The 2016 wildfire in Fort McMurray was the costliest disaster in Canadian history, forced the evacuation of all 88 000 residents, and destroyed 15 % of the town's the built structures. Re-entry was delayed after initial tests revealed elevated concentrations of organic and inorganic pollutants, including the toxic elements chromium (Cr), arsenic (As), and antimony (Sb). Currently, there are no studies that investigate how long wild-fire derived pollutants are retained in indoor environments, and if they represent a long-term health risk to residents.

Here, we report initial results from a house dust sampling campaign carried out 14 months after the fire. We collected house dust samples from the bedrooms of 35 houses using a modified vacuum cleaner. All analyses were conducted in the <150 µm size fraction. Trace elements were quantified by ICP/MS after total digestion with HNO3/H2O2/HF. We compare our house dust results with samples of urban and forest-floor ash collected during the Fort McMurray wildfire, background studies of Canadian houses in locations not affected by wildfires [Rasmussen et al., 2001, 2013], and regulatory guidelines (Alberta Tier 1 guideline for residential soils).

The concentrations of Cr, As, and Sb in house dust collected in Fort McMurray (geom. mean 48, 5.3, and 6.4 ppm) were comparable to those in background studies (geom. mean 101, 7.7, and 5.5 ppm [Rasmussen et al., 2001, 2013]. Ash concentrations of Cr, As, and Sb differed between urban and rural areas. Urban areas exhibited high concentrations (200-3000, 100-1300, and 20-300 ppm; n=3) that exceeded regulatory guidelines (64, 17, and 20 ppm), while concentrations in forest-floor ash samples were typically below those found in house dust samples (7-300, 1-12, and 0.1-3 ppm; n=5).

Overall, our results indicate that very high concentrations of Cr, As, and Sb can be found in ashes from urban, but not rural, areas; however, our data do not provide evidence that these elements persist in house dust over extended periods of time.

In-field Emission Measurements of Forced-draft Pellet and Traditional Wood and Charcoal Stoves in Rwanda.

WYATT CHAMPION, Andrew Grieshop, *North Carolina State University*

Nearly three billion people rely on solid fuel burning stoves that emit particulate and gaseous pollutants causing adverse health and climate effects. In Rwanda, 96% of all homes utilize solid fuels for cooking, and wood is the primary cooking fuel in nearly all rural homes (GACC, 2012). Household air pollution (HAP) is the fourth highest risk factor for morbidity and mortality in Rwanda, and respiratory infection is the leading cause of life lost.

The current study assesses the Mimi Moto forced-draft pellet-fed semi-gasifier cookstove in urban and rural homes in Gisenyi, Rwanda. The objective of the study is to compare emissions of the Mimi Moto to traditional wood (three stove fire) and charcoal (coalpot/Jiko) stoves. The Mimi Moto is distributed through a unique business model that promotes availability and affordability, and provides the stove, delivery, training, and repair at no cost.

Uncontrolled cooking tests (UCTs) were conducted in 22 homes (2 tests per home) during November and December of 2017. A follow-up deployment of equal size is scheduled for May 2018, for a total UCT sample size of approximately 90. The UCT has the advantage over other test types (e.g., Water Boiling Test, Controlled Cooking Test) of being relatively unobtrusive and likely more representative of actual cooking practices. The Stove Emission Measurement System (STEMS) was deployed and measured real-time concentrations of carbon dioxide (CO_2), carbon monoxide (CO), $PM_{2.5}$ light scattering and absorption, and integrated filter $PM_{2.5}$ mass and organic/elemental carbon (OC/EC). Filter analyses are on-going, and additional analyses will include real-time emissions data (MCE, SSA), and particle optical properties (B_{ap}, B_{sp}) with a comparison against filter measurements. Field UCT results will be compared against field WBT results sampled using the same equipment.

Preliminary results found the Mimi Moto to have a 5- and 16-fold lower median CO emission factor (EF, g/kg) compared to the wood and charcoal stoves, respectively. Compared to previous field cookstove emissions studies (Roden et al., 2006; Grieshop et al., 2011; Wathore et al., 2017), median CO EFs were around 10-20% and 30% lower for wood and charcoal, consistent with inter-test variability for these traditional fuels. The Mimi Moto CO EF (20 g/kg) was higher than previously reported laboratory test results (conducted by a different group), highlighting the common observation that field tests may represent more realistic and “dirty” events compared to laboratory test results. The Mimi Moto stove also had on average 8- and 3-fold lower median test-average $PM_{2.5}$ light scattering compared to the wood and charcoal stoves. The distributions of Mimi Moto CO and $PM_{2.5}$ light scattering data were asymmetrical, clustered around a low mean value with a long upwards tail, suggesting that potential low emissions are not always realized in the field. This finding underscores the importance of proper stove usage. Properly functioning Mimi Moto stoves were clean-burning. However poorly operated Mimi Moto stoves were, for at least $PM_{2.5}$ light scattering, as dirty as their well-operated traditional counterparts. This study gives field evidence that forced-draft pellet-fed gasifier cookstoves have great potential to reduce emissions (and exposures), but may be highly sensitive to operational conditions.

Exposure Assessment by Measuring Microbial DNA in House Dust using digital Polymerase Chain Reaction (dPCR).

ASHLEIGH BOPE, Samuel Cochran, David Kormos, Karen C. Dannemiller, *Ohio State University*

We spend 90% of our time indoors where we are exposed to diverse microbial communities. Much of this exposure results from house dust, which is resuspended from the floor due to occupant motion. This exposure may be assessed using quantitative Polymerase Chain Reaction (qPCR) using primers to specific microbial species of interest. Here, we explore the use of a new technology, digital Polymerase Chain Reaction (dPCR), as an advancement for measurement of this microbial DNA. Benefits of dPCR over qPCR include that it is less prone to inhibition and provides results in number of strands of DNA measured, potentially reducing the need for standards. To test measurement accuracy, we spiked known concentrations of *Aspergillus fumigatus*, *Escherichia coli* and *Bacillus atrophaeus* into carpet, vacuumed the dust, extracted DNA, and measured the quantity with dPCR. We determined that DNA was lost at each stage of the process, including vacuuming and DNA extraction. For instance, for *A. fumigatus*, 5% of DNA was lost in vacuuming from low pile carpet and 44% of DNA was lost in vacuuming from medium pile carpet. An additional 70% of DNA may be lost during DNA extraction. DNA extraction losses may be accounted for in qPCR through the use of appropriate standard, but could potentially be overlooked during dPCR. These results demonstrate the need to account for recovery efficiencies when using dPCR to measure microbial exposure from dust, or final results may be grossly underestimated.

Observed Levels of Particle and Gas Phase Pollutant inside School Classrooms with Varying Air-Conditioning Systems.

SUPREME JAIN, Divyam Garg, Anubha Goel, *Indian Institute of Technology Kanpur*

With the aim to examine air quality inside school micro-environments so that any possible health impact on students can be ascertained, a study was conducted inside two schools situated in the city of Kanpur, India which is one of the largest city (Inhabitants = 2.5 million) in the Indo-Gangetic plain. The two schools selected differed significantly in student strength, infrastructure, classroom size, ventilation system and proximity to the highways etc. Active air sampling inside classrooms was done continuously during the school timing (8:00 am to 2:00 pm) for particulate matter, and gaseous pollutants i.e. carbon monoxide (CO) and oxides of nitrogen (NOX).

In both schools, more than 99% of the sampling time PM10 mass concentration was higher than permissible limits (100 µg/m3 for ambient air) specified under National ambient air quality standards (NAAQS, India). The average PM10 mass concentration ranged between 200 to 240 µg/m3 during sampling hours (values ~ 2 times higher than permissible levels.) Type of ventilation system installed showed an impact on levels of respirable and finer particles with lesser levels observed in the school with a central cooling system. School which has air-conditioned classrooms were found to have PM3 concentration ~50% higher than permissible limits for PM2.5 (NAAQS, 60 µg/m3). The PM3 levels inside classrooms having a central cooling system were ~ 40% less than AC classrooms. Similarly in case of PM1 school having central cooling system had ~ 50% less mass concentration with respect to the AC classrooms. The average concentrations of gaseous pollutants (CO and NOx) were found to be within permissible limits during sampling hours. Influence of vehicular emissions in the vicinity of the school premises was observed through a sharp increment in finer particles and concentration of NOx inside the air-conditioned classroom during school opening and closing hours. Increased physical activity of the occupants inside classrooms was observed to raise the concentration of particulate matter but had less impact on the gaseous pollutants.

These observations highlight important role design of school building, and ventilation system, manmade or natural, installed play in affecting the indoor air quality. Chemical characterization of respirable particles is needed to enable realistic assessment of their impact on the health of the students. Diurnal variations in air quality in different microenvironments inside schools, such as playgrounds, library, canteen/ mess area, etc. need to be monitored and factors influencing levels and trends observed investigated. Lack of Indoor Air quality standards for different indoor micro-environments is another matter of concern and their development needs urgent attention.

4IM.2

Application of Particle and Aerosol Technology to CMP (Chemical Mechanical Planarization) Process Optimization.

TAESUNG KIM, Chulmin Shin, Seokjun Hong, *Sungkyunkwan University*

Chemical Mechanical Planarization (CMP) has become one of the most important and enabling semiconductor fabrication processes. Especially for logic devices, the number of CMP steps more than tripled from 28nm to 10/7nm node to enable complex integration schemes. However, there are still many aspects in CMP that have not been explained, which makes CMP rather art than science.

In this presentation, I will describe an effort to apply particle and aerosol technology to CMP process analysis to find a way to explain some of the phenomena more accurately. Firstly, Scanning Mobility Particle Sizer (SMPS), which is one of the standard instruments to measure particle size distribution, will be introduced for the measurement of slurry abrasive size distribution. Secondly, particle transport simulation with Computational Fluid Dynamics (CFD) will be introduced to predict pad debris transport between the wafer and pad, which can explain the pad debris trapping of laser drilled holes on the pad. Finally, new concept of pad debris removal to reduce scratch will be introduced.

4IM.3

Effect of O2/N2 Ratio on the Generation of Self-Charged Positive and Negative Sub 5 nm with a Glowing Wire. MICHEL ATTOUI, *LISA, Université Paris Est Créteil France*

Ultrafine particles generation with resistive heating wires (platinum, nickel, steel, tungsten etc…) in noble gases (argon, nitrogen, helium etc…) have been used since 1950s. Detection and sizing aerosol metrology (differential mobility analyzer coupled to atmospheric pressure mass spectrometers) highlighted the last decades that the lower limit in generated particles size of the method is around the atomic level.

The glowing wire method is mostly used with inert gases as carrier gases (nitrogen, helium or argon) to prevent contamination and especially oxidation.

Oxidation at high temperature on the other hand makes the wire very fragile and incapable to resist to a frequent breakages. However NiCr wire is the exception which is used in many industrial applications at high temperatures (ovens, heating, cooking etc…). This study focuses on the characterization of the glowing wire generator with a NiCr wire in a mixture of dry nitrogen-oxygen as carrier gas. The ratio of oxygen in nitrogen varies from 0 to 20 %.

The study is limited to sub 5 nm particles range in terms of size distribution of positive and negative self-charged particles with a high resolution DMA. The flowrate inside the glowing wire chamber varies from 10 to 50 lpm to prevent the growth of particles by coagulation.

4IM.4

Wide Size Range Number Concentration Calibration with Low Uncertainties. ANSSI JÄRVINEN, Jorma Keskinen, Jaakko Yli-Ojanperä, *Tampere University of Technology*

Aerosol instruments operate in a wide size range, which is a challenge in the instrument calibration. Different particle generation methods are used, and these require different concentration references. Instrument number concentration calibration in the small particle sizes, below 30 nm, is rather straightforward with different generation methods, bipolar charging and electrical classification with a Differential mobility analyser (DMA). Because at these sizes, particles acquire practically only one elementary charge, the Faraday-cup aerosol electrometer (FCAE) may be used as a reliable number concentration reference. The calibration size range can be extended towards larger particle sizes if multiply charging is minimized, but µm range is not typically achieved. The µm sized calibration particles are typically generated with completely different means. These methods do not produce singly charged particles, and as a result, different concentration references are used, for instance optical particle counters.

In traceable high accuracy calibrations, the step from the electrical reference to the optical reference is somewhat troublesome, because multiply charging limits the accuracy of the electrical method and the particle sizes below approximately 1 µm are problematic for optical particle counters as the detection efficiency may decrease. In addition, particle counters suffer from coincidence at high particles concentration, which limits the calibration concentration range. Thus, there is a need for a single calibration setup, which covers the size range from the smallest nm particles up to µm sizes.

To improve calibration accuracy in this problematic size range and to enable high concentration calibrations in µm size range, we have developed a calibration system relying on singly charged particles (Järvinen et al. 2018). The size range spans from nanometers up to micrometers, while the reference concentration is acquired from a FCAE. The developed system is an evolution of the Singly charged aerosol reference (SCAR, Yli-Ojanperä et al. 2010). The main principle is that singly charged seed particles are grown into larger sizes by condensing diethylhexyl sebacate (DEHS) on them. At large particle sizes, the process may also generate neutral particles, which must be removed with a DMA. To generate and classify µm sizes particles, a large sized DMA was designed and constructed. In a calibration measurement, large particles are divided between the instrument and the reference, which is sometimes challenging due to inertial losses. In our case, the concentration is equalized using a static mixer, which is followed by a flow splitter.

The operation of the calibration setup components was studied carefully. The particle growth was studied and DMA transfer function was measured. The major factors affecting the number concentration uncertainty were minimized and confirmed. The flow splitting was studied thoroughly with two identical FCAEs, and the bias between the inlet ports was observed to be small, less than ±1% from 3.6 nm up to 5.3 µm with uncertainty less than ±1% (k=2) at most of the size range at 1.5 l/min flow rate.

We used the developed setup in a calibration of a Condensation particle counter (CPC) detection efficiency. The detection efficiency was measured in the same size range with the bias, between 3.6 nm and 5.3 µm. The calibration uncertainty (k=2) was less than ±5% over the entire size range and less than ±2% between 5 nm and 4.3 µm.

A Post-Correction Method to Improve the Accuracy of the Aerosol Particle Mass Analyzer. BO-XI LIAO, Chuen-Jinn Tsai, *National Chiao Tung University*

The available technique for the direct mass measurement of sub-50 nm nanoparticles is limited at the present time, restricting the characterization of the particle mass, density, and related properties. The tandem differential mobility analyzer (DMA) and aerosol particle mass analyzer (APM) provides an efficient mass measurement for submicron particles, while the lower limit of the particle size for the DMA-APM technique is restricted at about 50 nm due to the APM mass underestimation. To advance the technique for sub-50 nm nanoparticles, a post-correction method with an empirical equation according to the value of $\lambda_{c,P}$ was proposed to correct the APM mass underestimation without any modification of the instrument. The correction method was applied to the mass measurement data of the silver nanoparticles measured at different APM operation conditions. It was found that the standard error of the data fitting was reduced by the correction, suggesting that the quality of the measured mass data was improved by the correction. Besides, the study also confirmed that the influence of the particle size, porosity, and morphology of nanoparticles on the accuracy of the APM should be minor.

A Numerical Model To Predict The Performance Of High Flow DMAs To Classify Sub-nm Aerosols. HUANG ZHANG, Girish Sharma, Yang Wang, Shuiqing Li, Pratim Biswas, *Washington University in St Louis*

As conventional Differential Mobility Analyzers (DMA) such as Nano DMA do not have high resolution for classifying sub 2 nm particles[1], a Half Mini DMA was designed and fabricated to overcome these limitations[2]. In this presentation, a numerical computation was carried out to study the flow details inside the Half Mini DMA, and compare its classifying abilities for sub 2 nm particles with the Nano DMA. Because the flow rate designed in Half Mini DMA is high, a theoretical analysis is first performed to determine the flow compressibility under different working conditions. Second, the governing equations of sheath flow and electric field were developed. A transport-diffusion equation was used to describe the aerosol flow in considering the particles in DMA as continuous materials. Third, COMSOL was used to generate triangular meshes of the computational domain and solve all the governing equations. The results show that the velocity is much higher in Half Mini DMA than that of Nano DMA. Further, the transfer function of 1 nm, 1.5 nm, 1.8 nm and 2 nm particles were validated by the experiments, and to show that the Half Mini DMA does have a high resolution with sub 2 nm particles. Finally, the particle residence time and particle convective flux distribution were performed to explain the working ability difference of these two DMAs.

Calibration of Centrifugal Particle Mass Analyzers (CPMAs) Using a DMA-Tandem-CPMA Technique. ZHEN LI, Jingkun Jiang, Da-Ren Chen, *Virginia Commonwealth University*

Instead of using the DMA-CPMA technique (i.e., a DMA is connected in series with a CPMA) often applied previous studies for the CPMA calibration, one DMA and two CPMAs were connected in series in this work to evaluate the performance of a CPMA (i.e., the particle penetration efficiency and the transfer function of a CPMA). This method is based on the operational principle of a CPMA, in which the centrifugal force acting on particles is balanced with the applied electrical force. The calibration of a CPMA should be directly based on the particle mass, not on the particle size classified by a DMA. In this DMA-tandem-CPMA experiment, particles of tested sizes were first selected by a TSI DMA. The mass-based size distribution of DMA-classified particles was then measured using the 1st CPMA. With the measured mass-based size distribution of DMA-classified particles, test particles of selected mass were classified by the 1st CMPA operated at fixed voltage and rotational speed. The test particle steam was then directed into the 2nd CPMA operated at the same rotational speed as that of the 1st CPMA while varying its voltage in an entire applicable voltage range. A condensation particle counter (CPC) was utilized to measure the concentration of particles exiting the 2nd CPMA. Polydispere solid particles of various materials were generated by spraying solutions of test materials via a custom-made Collison atomizer and drying generated droplets in a diffusional dryer.

We found that in the cases of particles with the mobility diameter larger than 100 nm, the particle mass measured by the 2nd CPMA was in general less than 10% of that classified by the 1st CPMA when test particles were selected from the right-hand side of mass-based particle size distributions. The particles mass measured by the 2nd CPMA agreed well with that classified by the 1st CPMA when they were selected from the left-hand side of the mass-based size distribution. In the cases of particles in the mobility diameters less than 100 nm, the particle mass measured by the 2nd CPMA were in general larger than 15% of that classified by the 1st CPMA when selected from the left-hand side of mass-based DMA-classified particle size distributions. Reasonable agreement between the classified and measured particle mass was observed when selected from the right-hand side of the mass-based particle size distributions.

Based on the measured particle penetration efficiency in the experiment, the transfer function of a CPMA were evaluated via a piece-wise linear inversion scheme with the assumption of the same CPMA transfer functions of both used CPMAs. The details of this work will be presented in the conference.

Characterization and Performance of the Caltech-ADI Portable Scanning Electrical Mobility Spectrometer. STAVROS AMANATIDIS, Huajun Mai, Changhyuk Kim, Richard Flagan, Steven Spielman, Gregory Lewis, Susanne Hering, *California Institute of Technology*

In this study, we present the detailed characterization and preliminary performance of the *Caltech-ADI Scanning Electrical Mobility Spectrometer (SEMS)*, a newly developed and highly portable particle sizer designed primarily for planned atmospheric studies.

The instrument combines a novel, compact radial-flow Differential Mobility Analyzer (DMA) developed at Caltech, and a self-sustaining, motion-tolerant, water-based condensation particle counter (WCPC) designed by Aerosol Dynamics Inc. The system operates at low flowrates (0.6 – 0.9 L/min, and 0.3 L/min for sheath and aerosol flows, respectively), and provides particle sizing in the 10-500 nm range with resolving power on the order of 2-3; this resolution and these flow rates are sufficient to attain the precision and counting statistics required for atmospheric measurements. The reductions from traditional operating parameters in SEMS measurements has enabled dramatic reductions in the volume, weight, pumping, and power requirements (<5kg, <50W).

The transfer function of the radial-DMA has been determined over the operating range of sheath/aerosol flows and voltage using highly monodisperse NaCl particles in the 10-500nm range. Moreover, we have explored the effect of voltage scan time to determine the extent to which the transfer function is smeared due to the delay time distributions in the plumbing and WCPC. This is especially important for Unmanned Aerial Vehicles (UAV) measurement applications where fast scans (<30s) are required to attain good spatial resolution of the atmospheric aerosol properties. The results are compared to theoretical transfer functions, as well as simulated ones calculated using COMSOL 3D finite element modelling. Further, based on the experimentally determined transfer functions, we compare the Caltech-ADI SEMS to a benchtop Scanning Mobility Particle Sizer (SMPS) in measuring ambient aerosol particle size distributions.

4IM.11

Mobile Chasing Measurement of Black Carbon and Nitrogen Oxides Emissions from Heavy-duty Vehicles in China.

SHAOJUN ZHANG, Hui Wang, Ye Wu, K. Max Zhang, *Cornell University*

The measurement techniques of vehicle emissions have achieved substantial advances in recent years, which have spurred the progressive implementations of stringent emission regulations. Notably, portable emissions measurement systems (PEMSs) have played an essential role in regulating real-world vehicle emissions. However, although the PEMS testing method has the useful features, the expensive instrumental cost and long experimental duration may become limitations to measure emission factors of massive on-road vehicles. Thus, we see a need for cost-effective and fast-response vehicle emission measurement methods to be developed and improved. In this study, we integrated a mobile measurement platform by equipping one Mini Van with multiple high-accuracy analyzers for measuring instantaneous concentrations of CO_2, CO, NO/NO_X, particle number, and black carbon (BC). For example, one EcoPhysics Analysator (Model CLD66) was applied to record continuous NO_X concentration profiles on the road, while one Aethalometer (Model AE-33) was used to measure real-time BC concentration. According to the concentration elevation ratios of targeted pollutants to CO_2 compared with road environmental baselines, fuel consumption-based emission factors of individual trucks are estimated. Comparative studies were conducted between PEMS and mobile chasing for BC and NO_X emission factors of typical diesel trucks, which provided sufficient evidences for the effective measurement of real-world emission factors using the mobile platform.

This mobile platform was further applied to measure emission factors of on-road diesel trucks on highways. During 2017 and 2018, we launched a large-scale field study in several provincial regions of China (e.g., Beijing, Tianjin, Hebei, Henan and Sichuan), in which nearly one thousand trucks were measured by chasing on typical highways. Our preliminary results show the China IV diesel trucks could effectively reduce BC emissions than the older China III trucks. Nature gas-powered trucks and buses emit significantly lower BC than the diesel engines by at least one order of magnitude. However, relative to China III diesel vehicles, we could find no significant improvements in NO_X emission factors for either China IV diesel trucks using selective catalytic reduction or nature gas fueled vehicles. These findings have highlighted great challenges to control NO_X emissions from modern heavy-duty fleets in China and will be useful to update road emission inventories.

4IM.12

A PPWD-SDEP-IC System for Hourly Measurements of Ambient PM2.5 Inorganic Ions and Precursor Gases. CHI-YU TIEN, Chao-Ting Hsu, Ssu-Yin Lai, Yung-Chen Chiang, Chuen-Jinn Tsai, *National Chiao Tung University*

A 2-stage Semi-Dry Electrostatic Precipitator (SDEP) was developed and integrated with the parallel plate wet denuder (PPWD) and IC as a PPWD-SDEP-IC system for hourly monitoring of $PM_{2.5}$ inorganic ions and precursor gases measurement. Carbon fiber bundles are used as the discharge electrodes in the first stage to lower the background concentrations of NH_4^+ and NO_3^- which are artifacts due to corona discharge of the traditional EP. The second stage of the SDEP is to collect charged particles in the electric field. The SDEP has the particle collection efficiency as high as 93-100 % for 14-700 nm NaCl particles generated in the laboratory at the operating flow rate of 5 L/min, and $PM_{2.5}$ collection efficiency of 98.1 % for incense smoke (MMAD of 241 nm). The inorganic ion recovery efficiencies of lab-generated non-volatile particles (Na_2SO_4, $(NH_4)_2SO_4$) and volatile particles (NH_4NO_3) are very good, which are 95% for Na^+ and 90% for SO_4^{2-}, 110 % for NH_4^+ and 90 % for SO_4^{2-}, as well as 107% for NH_4^+ and 99% for NO_3^-. By combining the $PM_{2.5}$ inlet, SDEP, PPWD, IC and automatic extraction and injection system, the PPWD-SDEP-IC system was demonstrated to have a very good performance for ambient $PM_{2.5}$ inorganic ions and precursor gases monitoring in the field comparison tests in which manual porous metal denuder sampler (PDS) and honeycomb denuder sampler (HDS) were used as references.

Keywords: PPWD-SDEP-IC, electrostatic precipitator, $PM_{2.5}$, aerosol sampling, inorganic soluble ions

Ultrahigh Resolution Orbitrap Elite Mass Spectrometry Reveals Unprecedented Molecular Detail in Atmospheric Aerosol. LYNN MAZZOLENI, Simeon Schum, Matthew Brege, Tyler Leverton, Elizabeth Rose, Maryam Khaksari, *Michigan Technological University*

Atmospheric organic aerosol is a very complex mixture containing components ranging from hydrophobic condensed aromatics to highly oxidized molecules. The compounds include C, H, N, O, and S, where N and S can exist in either oxidized or reduced forms. Ionization methods control what type of molecules are introduced into a mass spectrometer, thus a variety of ionization methods can be used for an accurate assessment of the overall organic aerosol composition. Specifically, the combination of electrospray ionization and atmospheric pressure photoionization is ideal for widespread coverage. Identification of unambiguous molecular formulas for accurate mass measurements requires low measurement error and sufficient mass resolution to separate common isobars. One of the commonly observed isobars in atmospheric aerosol involves molecular formulas that differ by 3.4 mDa due to the exact mass difference of C3 vs. SH4.

The ultrahigh resolving power of the second-generation high field Orbitrap Elite mass spectrometer (R = 240,000 at m/z 400) is sufficient for separation of common aerosol compositional isobars up to ~ 500 Da permitting an accurate assessment of S-containing compounds. The accurate mass measurements of the Orbitrap Elite can be further improved using a combination of custom internal and external calibration methods to refine the assignment of unambiguous molecular formulas. This is especially critical for compositions that include N and S, since the number of possible equivocal molecular formulas increases with increasing molecular weight. Thus, accurate mass measurements with less than 1 ppm mass error are needed to reduce the equivocal formulas.

In this presentation, we will demonstrate the power of ultrahigh resolution Orbitrap Elite mass spectrometry (MS) measurements with a focus on new ionization methods that provide new insights on the detailed molecular composition of ambient organic aerosol. We also present unprecedented molecular complexity using a segmented scanning approach with ultrahigh resolution MS/MS. These results suggest that a wide range of components from hydrophobic condensed aromatics to highly oxidized molecules are present in the aqueous extracts of organic aerosol. A more thorough understanding of organic aerosol composition is vital for an improved estimation of aerosol properties and studies involving fate and transport of pollutants.

Particle Measurement Under High Pressure Conditions on a Combustor Test Rig. Frank G. Bachman, TRISTAN REINISCH, Bill Silvis, Richard W. Frazee, Alexander Bergmann, *GE Aviation*

Until now, the only fundamental aerosol measurement approach available for an aviation turbine engine involves aerosol measurements taken at the exit plane of the aviation engine via fundamental particle measurement techniques. As the non-volatile aerosol measured at the exit plane of an aviation engine originates in, and is generated by, the combustor, it is highly desirable to be able to measure the aerosol at the exit plane of the combustor. The scientific drive, along with activities in the emissions legislation arena for aircraft engines, motivated us to investigate a particle measurement approach allowing for the measurement of the aerosol at the combustor exit plane.

We introduce a pressure reduction unit which is optimized for particle measurements applicable to the emission characteristics at the aviation turbine engine combustor exit plane. Particle loss mechanisms are considered and countermeasures reduce their influence. Particle Number Concentration, Particle Mass Concentration and Filter Smoke Number are the quantities used for characterization.

The pressure levels in a combustor of an aircraft turbine engine are much higher than those encountered in other typical combustion processes (e.g. internal combustion engines), where particle emissions are relevant and regulated. The commonly used measurement equipment is not designed to operate under such conditions. Thus, there is a need to reduce the pressure of a combustor exit plane aerosol sample to ambient conditions. A pressure reduction unit with critical flow elements was engineered and characterized on a combustor test rig at GE Aviation.

The pressure independent results for non-volatile particle matter were compared to a proprietary Filter Smoke Number based system, developed by GE Aviation, which is specifically designed to measure at sampling system pressure levels above ambient pressure. In this study, we prove that the pressure reduction unit for particle measurement equipment operating at ambient pressure conditions fulfills all our requirements. We also prove that further measurement results are reproducible and comparable throughout the typically encountered operating fuel-air-mass ratio range of the combustor. This gives the opportunity to use the results for further combustor development, specifically the ability to design the combustor to specific nvPM requirements. To show also that this instrument can be used to investigate the emitted soot particles with respect to morphology, we took samples for Raman spectroscopy. The results show highly graphitized carbon with sp^2 hybridization which is typical for soot particles produced under high pressure conditions.

4IM.15

Evaluation and Sampling Efficiency of the Wet Dust Sampler (WDS) - a Water-based Method for Road Dust Sampling.

JOACIM LUNDBERG, Göran Blomqvist, Mats Gustafsson, Sara Janhäll, Ida Järlskog, *VTI*

Emissions of PM is a well-known problem, with great impact on human health. One of the largest contributors is the road traffic. Due to stricter regulations for exhaust emissions, the relative importance of non-exhaust emissions is increasing. Abrasion wear of both pavements, tyres and brakes contribute to non-exhaust emissions. These particles are both directly emitted but also accumulated on the road surface as road dust load. This road dust is suspended through the road surface and tyre interaction as well as the turbulence introduced by the vehicle.

To allow for studies of the emission potential for road dust, the road dust load must be quantified. To quantify the total available dust load, a measurement device, the Wet Dust Sampler (WDS) [1] was developed. The WDS has since its development been used extensively for measurements in Sweden and has since then been updated. This updated version has also recently been exported to Norway and Finland.

The WDS basic principle of operation is to perform high pressure washing of a defined road surface area. This washing can be performed using regular water, or to allow for chemical analyses, distilled water. The sample is transferred into a storage container by the means of compressed air.

Studies of how the machine and the settings used impact on the cleaning and sampling efficiency include several tests of the performance of the newest version. Features tested have been e.g. the repeatability of flushed water, the repeatability of collected water, the cleaning efficiency and the retention of dust in the system.

One of the initial studies focused on the cleaning efficiency in which repeated sampling was performed in the same point. This was done for three different pavements of type Stone Mastic Asphalt (SMA) with maximum nominal aggregate size of 16, 8 and 6 mm. These pavements were selected based on common usage in Sweden (mainly larger sizes) due to their resistance against abrasion from studded tyres. This study was performed in a laboratory setting with laboratory manufactured slabs of pavement. The road surface texture was then filled with a well characterised dust of known source.

The initial, limited results show indications of a high cleaning efficiency, all having less than 10% retained material after the first sampling.

Further results regarding

Investigating Effects of Ambient Gas on the Ionization of Compounds by Secondary Electrospray Ionization Using Ultrahigh Resolution Mass Spectrometry. JIAFA ZENG, Kai Wu, Rui Du, Yuling Zhang, Dandan Huang, Zhen Zhou, Xue Li, *Jinan University*

Secondary electrospray ionization (SESI) is a soft ionization technique, which occurs under ambient conditions; samples can be directly ionized without pre-treatment. A wide variety of organic compounds, such as fatty acids, aldehydes, ketones, alcohols and alkenes, have been successfully detected by using SESI mass spectrometry (SESI-MS) based methods. The ambient gas in the SESI source can affect the ionization efficiency of target compounds and interfering chemicals (e.g., plasticizers), which is closely related to the sensitivity of the method. In this study, volatile organic compound (VOC)-free dry-air and pure nitrogen gas (N_2, purity 99.999%) were selected as the ambient gases in the SESI source, and the effects of different ambient gases on the detection of typical exhaled VOCs (indole and acetone) in human breath and interfering compounds (dibutyl phthalate and polysiloxane) were systematically studied by using ultrahigh resolution mass spectrometry. The preliminary results indicate that the signal intensity of indole and acetone were enhanced at the presence of dry-air and N_2, and the enhancing effects were higher when N_2 was used. In contrast, the signal intensity of dibutyl phthalate and polysiloxane were greatly decreased, especially when N_2 was present in the source. Effects of dry-air on the detection of other exhaled endogenous compounds and interfering chemicals are still under investigation and the flow rate of the ambient gas delivered into the source is also tested in the present study. The study will provide helpful information on the optimization of SESI source and benefit a better understanding of SESI process, which is essential for improving method sensitivity.

Charge Distribution Characterization of an Indirect Ionization Soft X-ray Operated under Various Test Gas Environments. SIQIN HE, Derek Oberreit, *Kanomax FMT, Inc.*

Based on measuring mass (m) to charge (z) ratio of samples, mass spectrometry (MS) techniques have their analysis performance rely on reliable and steady ionization methods. The Chemical Ionization (CI) technique, as one of them, has been favorably used to study organic species in gaseous and particle phases because of its gentle ionization, reduced fragmentation, and flexible ion polarity selection during the ionization process. The operation of CIMS requires a bipolar ion source to generate positive or negative reagent ions, where the radioactive ion sources Am241 and Po210 have been commonly used in virtue of their simple operation and steady charge distribution, which meanwhile also limits the use of CIMS in field due to the safety regulations over radioactive sources. To facilitate the application of mass spectrometry analysis technique in field measurements, new ionizers have been developed based on soft x-ray ionization as an alternative source for such aerosol particle measurements that require bipolar charge conditioning, and its potential to be utilized in different operation environments is of great interest.

The ionization performance has been proven to be significantly influenced by the charging environment, e.g. the polarizability and properties of ionizing gas, the moisture level, and the chemical vapor content. In this study, the indirect ionization soft x-ray charge conditioner was evaluated by investigating its charge distribution when ionizing H2O or amine molecules in various test gases, including clean dry air (CDA), high-purity nitrogen (N2), high-purity carbon dioxide (CO2), and Argon (Ar). In addition, the transporting tubing material has also been reported to have an effect on charge conditioning performance, so a measurement comparing charge distribution of this soft x-ray charge conditioner with or without silicone tubing was also conducted and reported.

Performance Study of the HR-ELPI+ Instrument. Sampo Saari, ANSSI ARFFMAN, Juha Harra, Topi Rönkkö, Jorma Keskinen, *Tampere University of Technology*

Data inverting methods in aerosol measurement instruments have significant influence on the resolution and quality of the result. A new ELPI instrument, High Resolution ELPI+ (HR-ELPI+, Dekati Ltd.) uses a modern iterative inversion calculation method to improve particle size resolution and data analysis. In this study (Saari et al., 2018), the performance of the HR-ELPI+ is critically analyzed by simulations and experiments in the laboratory and field conditions, and the results are compared to the conventional inversion data analysis method (cut-point diameter concept) and common reference instruments (e.g. SMPS, EEPS).

Operating principle of the HR-ELPI+ is the same as ELPI+ operation added with the data inversion software. The data inversion calculation method is based on the kernel functions (Järvinen et al., 2014) and iterative calculation routine resulting in determination of particle size distribution with enhanced resolution. The inversion calculation runs in real-time and is simple to use and do not require any adjustments nor optimizations from the user of the instrument.

The simulation studies included the effects of two different sources of noise: 1) signal dependent noise by variation of concentration, 2) constant electric noise by electrometer. To find out the effect of the particle size, GMD of the simulated aerosol varied from 5 nm up to 9000 nm (GSD was fixed to 1.5). To study the effect of the GSD of the simulated aerosol, GSD values were tested between 1.01 and 2 (GMD was fixed to 100 nm). To investigate responses against multimode particle size distributions, a typical bi-modal (nucleation and soot modes) particle size distribution from a heavy-duty diesel truck engine and typical atmospheric aerosol modes (nucleation, soot, accumulation and coarse mode) were simulated and tested.

In the laboratory experiments, performance of the HR-ELPI+ was tested against dioctyl sebacate (DEHS) and NaCl aerosol generated using a nebulizer. Typical diesel exhaust aerosol from a passenger car on a dynamometer was tested in the field experiments. Experimental set-up consisted of parallel test aerosol measurements with the HR-ELPI+ and other reference instruments. The reference instruments were Engine Exhaust Particle Sizer 3090 (EEPS, TSI Inc.), two Scanning Mobility Particle Sizer Spectrometer: nanoSMPS (TSI Inc.) and longSMPS (TSI Inc.) and high-resolution low-pressure cascade impactor (HRLPI, Arffman et al., 2014).

Simulations showed that the HR-ELPI+ inversion performs accurately for lognormal unimodal and multimodal size distributions in the size range of 10 nm – 9 µm. Experimental results confirmed the simulated performance with laboratory test aerosols and field measurements. The results also indicated that the performance of the HR-ELPI+ may suffer if the raw currents have electrical noise more than 1%. However, the HR-ELPI+ clearly produces better resolution and quality with a low oscillation risk compared to the conventional cut-point diameter concept of ELPI. The HR-ELPI+ also generally showed very similar size distributions and concentrations compared to the EEPS and SMPS reference devices.

A Shaker Fluidized-bed Atomizer (SFA) for Nanopowder Dispersion with Stable Aerosol Concentrations.

CHI-YU TIEN, Wen-Cheng Gong, Chuen-Jinn Tsai, *National Chiao Tung University*

This study aims to develop a nanopowder disperser to generate aerosols with stable concentrations in long period of time. The home-made nanopowder disperser, called shaker fluidized-bed atomizer (SFA), consists of a dry aerosol atomizer, a nanopowder fluidization chamber and air-flow distributor. At the nanopowder fluidization chamber, 1 g of tested powder is placed. The main function of the air-flow distributor is to make sure the bulk nanopowder is fluidized and aerosols are suspended in the chamber uniformly. The suspended particles are sucked into the atomizer at the top of the chamber and de-agglomerated by high velocity jet from the critical orifice. As a result well-dispersed fine particles are generated. The size and mass distributions of dispersed particles were analyzed using SMPS and NCTU micro-orifice cascade impactor (NMCI), respectively, and particle morphology was observed by the TEM.

The results showed that the multi-wall carbon nanotube (MWCNT) aerosols dispersed by the SFA was stable in number, mass and surface area concentrations during 8-hr period. Both the size and mass showed the bimodal distributions with the mode diameter 165 and 453 nm, and MMAD of 0.18 and 1.28 µm, respectively. The TEM images displayed that MWCNT particles collected on the lower stage impactor were well dispersed and showed single-fiber like structure. Different kinds of nanopowders will also be tested in the future for further accessing the performance of the SFA.

Keywords: Nanopowder disperser, SFA, MWCNT

Calibration of Condensation Particle Counters Against an Aerosol Electrometer Over a Wide Range of Sizes with Minimal Charge State Uncertainty. JONATHAN SYMONDS, *Cambustion*

The use of a Faraday Cup Aerosol Electrometer (FCAE) as a reference standard for Condensation Particle Counter (CPC) calibration is a long-established technique which has been recently codified as part of ISO27891:2015. Using a FCAE is attractive as it exhibits high detection efficiency, independence from particle material and morphology, and is clearly traceable to primary standards. However, its accuracy relies on the assumption that each particle entering the FCAE possesses just one elementary charge. Given a Differential Mobility Analyzer (DMA, referred to in the standard as a Differential Electrical Mobility Classifier, DEMC) is used to size select particles prior to the FCAE and CPC under test, it is possible for particles of the intended electrical mobility, but of larger size and with more than one elementary charge to pass through the DEMC. These will not only be counted by the FCAE as more than one particle, but by being larger, will bias the size dependent counting efficiency curve. The standard describes mitigating this by taking great care as to the size distribution of source aerosol used, or to measure or calculate the fractions of multiply-charged particles. The technique below follows the mitigation route.

The primary source is a nebulizer, here filled with dioctyl sebacate giving a peak size ~320 nm and σ_g=1.9. Between the aerosol source and the “charge conditioner” (neutralizer) is placed an Aerodynamic Aerosol Classifier (AAC, Tavakoli and Olfert, 2013). This selects monodisperse aerosol at high resolution by aerodynamic diameter rather than electrical mobility, and is thus not affected by particle charge. The AAC is set to the same equivalent aerodynamic diameter as the DEMC’s mobility diameter (converting using the known aerosol density). The DEMC is hence only fed with monodisperse aerosol at the desired mobility size, and populations of particles at sizes greater than desired corresponding to higher charge states are effectively eliminated. Although it is possible to use a second DEMC and neutralizer in this role, this would only attenuate the higher charge populations in proportion to the charging efficiency of the neutralizer, still leaving uncertainty.

Data is presented showing a TSI 3775 CPC compared with a TSI 3068B FCAE over a size range of 50 nm–1.8 µm, showing a mean detection efficiency of 98%. This upper size, beyond the normal range of the TSI 3801 DMA used, is achieved by dropping its sheath flow. This resulting reduced resolution of the DEMC does not matter as the size accuracy and resolution desired to generate an efficiency curve is achieved by the AAC: the DEMC is required only to remove the uncharged and multiply-charged particles.

The technique is automatable given a single aerosol source can be used over a wide range, as there is no requirement for a close relationship between raw aerosol size and that selected in the DEMC. A continuously variable rotating disc diluter was used to keep the raw aerosol concentration within the optimal band for both the CPC and the FCAE. Although the lower limit of the current AAC instrument is 25 nm, below this multiple charging is not significant.

ISO27891:2015 also provides for calibration of a CPC against a reference CPC. In this case, there is no requirement for the aerosol to be charged, and an AAC can replace the DEMC. This is potentially useful in field calibrations where regulation prevents the use of radioactive or X-ray sources, and is possible up to the AAC size limit of ~6 µm. The technique is used to show that for particles >3 µm, single particle counting in the 3775 CPC breaks down.

Study of HR-ELPI+ Data Inversion with Porous Collection Substrates. ANSSI ARFFMAN, Ari Ukkonen, Anssi Järvinen, Sampo Saari, Esa Luntta, Ville Niemelä, *Dekati Ltd., Kangasala, Finland*

In this study, the effect of porous collection substrates on the data inversion algorithm of the HR-ELPI+ (Dekati Ltd.) was explored. The operation and verification of the inversion algorithm has been described and evaluated earlier for smooth collection plates (Saari, 2018). The porous collection substrates have been used in impactors to avoid particle bounce and to increase the loading capacity (e.g. Reischl & John, 1978; Van Gulijk, 2003; Tsai, 1995). The probability of particle bounce decreases and the loading capacity increases especially when oil is added to the porous collection substrate. The oil creates a sticky surface preventing the particle bounce, and the porous surface structure provides micro reservoirs for the oil, thus, keeping the impaction surface sticky even after several layers of particles has formed on a top of the collection substrate. The porous collection substrate also reshapes the impactor collection efficiency curve compared to a smooth or a plain surface. The cut size shifts to smaller size, the collection efficiency curve is less steep, and the fine particle losses will increase (see, e.g., Marjamäki, 2004). The increased losses influence to the 'tail' of the collection efficiency curve and also introduce the so-called excess collection efficiency in the sub-cut point particle size range as described in detail by Huang et al. (2001).

As stated earlier, the porous collection substrates decrease the cut points and reduce steepness of collection efficiency curves. Thus, it is important to evaluate how these changes affects to operation of inversion algorithm and results obtained when smooth collection plates are replaced with porous ones. The performance of HR-ELPI+ inversion was studied by numerical simulations and experimentally in lab conditions. The measured cut-sizes, collection efficiency curves, and fine particle losses for porous substrates were used in both studies.

In simulations, first, the theoretical current response of the ELPI+ for a log-normal size distribution was calculated and then the HR-ELPI+ inversion was used to calculate backwards the initial input size distribution. The results were then compared to the initial size distribution. In the experimental tests, the test aerosol generated from DEHS oil was measured with the HR-ELPI+ equipped with sintered metal substrates and the results were compared to the measurement results of the HR-ELPI+ with the normal smooth collection plates.

The simulation results showed that in the size range of 20 to 1000 nm the difference in number concentration between the inverted and the input concentration was 6% in maximum. For size distributions with GSD 1.3 or larger, the differences were smallest and the maximum differences were observed for narrow size distributions. The experimental tests showed that the similar accuracy can be achieved also in practice for evaporation-condensation method generated DEHS aerosols. Overall, results showed that the HR-ELPI+ inversion can be successfully used to retrieve the high resolution input size distribution although the porous metal collection substrates change the collection efficiency curves of the ELPI+ impactor in large extent.

Comparison of the TSI 1-nm and Standard Scanning Mobility Particle Sizers during the Lake Michigan Ozone Study.

MEGAN CHRISTIANSEN, Charles Stanier, Sherrie Elzey, Nathan Janechek, Nathan Bryngelson, Maynard Havlicek, Andrea Tiwari, *University of Iowa*

During the Lake Michigan Ozone Study 2017 (LMOS 2017), the aerosol size distribution was measured for a 1-month period at Zion, Illinois, a site on the Western shore of Lake Michigan. The purpose of the field study was to establish an observational database for improved understanding and model-measurement evaluation of regional and local ozone episodes. Aerosols were monitored as a source apportionment and monitoring site characterization tool, together with extensive meteorology, remote sensing, and in-situ gas-phase monitoring. The study ran from May 22 – June 22, 2017.

The study was used as an opportunity to compare the widely used and well-established "long DMA" configuration of TSI's Scanning Mobility Particle Sizer (SMPS™ with model 3081 DMA column paired with model 3785 CPC), against a newly developed commercially available model 3938E77 1-nm SMPS capable of 1-nm sizing. The 1-nm SMPS combines a model 3086 1-nm DMA, model 3777 Nano Enhancer with diethylene glycol working fluid, and model 3772 CPC with butanol working fluid. The 3777 Nano Enhancer uses diethylene glycol to pre-grow particles to ~ 100 nm for CPC detection.

During a majority of the sampling campaign, the 1-nm SMPS was well correlated with the standard SMPS in the overlapping size range of 12 to 32 nm. Preliminary data analysis indicates that within the overlapping range, the mean particle concentrations were 1956 cm^{-3} (1-nm SMPS), 1272 cm^{-3} (standard SMPS), with a correlation coefficient (r) of 0.93. The correlation coefficient is calculated based on paired hourly data pairs (n=537). Counts were significantly higher on the 1-nm SMPS at sizes less than 20 nm, with increasing divergence between the instruments as size decreased. This is in part due to differences in inlet flows and particle losses between the two instruments.

Several nucleation and growth events were detected with this 1-nm SMPS configuration, with particles detected down to 1.2 nm geometric mean diameter. These events will be placed in context with the 3D and 2D wind fields measured at the site (by SODAR and anemometer, respectively), as well as high time resolution radiation and gas-phase measurements (VOCs, NOx, SO2, nitric acid). The percentage of hours with number concentrations greater than 50 cm^{-3} using the 1-nm SMPS in the 1 to 3, and 5 to 10 nm size ranges, was 28% and 73%, respectively.

Ongoing data analysis will further explore the above, as well as any differences in the size distribution caused by drying the standard SMPS while leaving the 1-nm SMPS undried. Finally, periods of very high, and seemingly non-physical, counts detected by the 1 nm SMPS will be explored.

Effect of Eccentricity on the Performance of a Cylindrical Differential Mobility Classifier. THAMIR ALSHARIFI, Da-Ren Chen, *Virginia Commonwealth University*

Scanning/differential mobility particle sizers are now commonly used in aerosol community to characterize the size distribution of submicrometer particles in gases. A differential mobility classifier (DMC) is the key component in the sizers for sizing particles. In the DMC design, it is required to provide the tolerance at least on all the key dimensions of a DMC when the mechanical drawing is produced for machine shops. The tolerance requirement in a DMC design also affects how the DMC is constructed. It is therefore very important to understand the design/construction imperfection on the performance of a DMC. Differential mobility classifiers in various configurations have been designed and evaluated in the literatures. Among different configurations, DMCs in the cylindrical design is the most popular ones because of no side-wall effect encountered in parallel-plate DMCs and their successfully commercialization. As the first step in a series of investigation, this study focused on the effect of eccentricity on the performance of a cylindrical DMC. Numerical approach was taken in this study. COMSOL was applied in the numerical modelling.

In this study, we investigated the effect of eccentricity on the performance of different cylindrical DMCs operated at different aerosol and sheath flow rates. The geometrical parameters of studied DMCs include the diameters of inner and outer cylinders, the length of particle classification zone, and the angles of aerosol entrance and exit. Prior to the parametric study, our modelling result was validated by the comparison with the theoretical transfer function given by Knutson & Whitby (1975). The theoretical transfer function derived by (Knutson, 1972) for an eccentric DMC in the cylindrical design was also included in the comparison.

Our study shows that, because of the eccentricity, the DMC transfer function was deteriorated as the eccentricity increased for Nano-DMA. The peak of DMC transfer function would split into two peaks as the eccentricity (defined as the off-center distance to the annular spacing between two cylinders) is more than 5%. This two-peak appearance of the transfer function would occur at the less eccentricity as the classification length of DMCs. However, the effect of eccentricity would be reduced as the annular spacing between outer and the inner cylinders was increased. More details of our study will be presented at the conference.

Effect of Change in Sheath Air Humidity on Size Distribution Measurements by Scanning Mobility Particle Sizer. B.K. SAPRA, Mariam , Manish Joshi, Arshad Khan, *Bhabha Atomic Research Centre, Mumbai*

Scanning mobility particle sizer (SMPS) is widely used for measurement of size distribution of sub-micrometer particles in atmospheric and laboratory applications. Sheath air flow inside Differential mobility analyser of SMPS provides laminarity for aerosol particle stream flow. This work investigates the effect of sheath air dryer in the measurement of size distribution of particles with varying hygroscopicities. Aerosol particles of three different materials i.e. NaCl, $NaNO_3$ and nichrome generated by nebulization/electrical heating were sampled through a twin SMPS system from a controlled chamber of volume 40 L. As the particles (of NaCl, $NaNO_3$) generated from nebulization showed geometric mean diameter between 100-150 nm, nichrome nanoparticles were also allowed to grow in the same size range. One of the SMPSs of twin SMPS set-up had modified sheath air path (by keeping dryer in circuit) while the other was kept as such in a T-joint arrangement taking simultaneous sample from the chamber. Three sets of experiments were performed for each type of particle system at 3 different (chamber) relative humidity (RH) levels (15%, 40% and 90%). For the case of NaCl particles, 52.2±0.48% decrease in relative geometric mean (GM) of distribution measured by SMPS with sheath air dryer was seen at 90% RH. No such difference was noted for other RH levels (lesser than Deliquescence RH: 75.3% (Pilinis and Pandis, 1995). $NaNO_3$ particles did not follow any deliquescent behaviour (Hu et. al., 2010, Lee et al., 2011), and showed growth at lower RH (40%, 60%) levels as well. Size distribution of Nichrome metal particles measured by both SMPSs remained unperturbed at all RH levels. Experimentally measured changes in GM diameter for the case of nebulized particles were also found to be reasonably matching with KÖhler theory predicted values. Since there is no clarity on protocols for usage of sheath air dryer for SMPS measurements; correction factors, algorithm modifications, newer protocols are required to be incorporated for size distribution measurements.

SEMS Transfer Functions under Fast Sequential Scanning. MARK KANAPARTHI, Suresh Dhaniyala, *Clarkson University*

The size distribution measurements are routinely made using a Scanning Electrical Mobility Spectrometer (SEMS). These measurements are generally made over a reasonably long time period (large scan time). With decrease in the scan time of the operation, the discrepancy between the classically predicted transfer function and the actual transfer function is more pronounced. As the scan time approaches the average residence time of the particle in the classifier section, an increasing fraction of particles that are injected during the scan are extracted in the successive scan. To calculate the transfer function under such conditions, the traditional trajectory approach by Dubey and Dhaniyala (2008) can't be employed since the particles encounter a combination of an exponentially increasing voltage with an exponentially decreasing voltage, i.e. the Arrival time Transfer Function (ATF) can't be translated in time as was done previously. The ATF's have be calculated for every mobility to compute the mobility transfer function. The mobility transfer function computed is used to calculate the instrument response. The implications of inverting data under a combination of up-scan and down-scan is discussed.

Performance of Fundamental Functional Feature on DMA (2). CHIRYO TSUNODA, *FES*

In the previous presentation, we have known that the performance of functional feature on DMA have given two typical important data. The linear data have already explained, hereinafter, we would like to explain with the non-linear data for the performance of the new response function of DMA.

Encouraged by the successful theoretical and mathematical description for the performance of the response function of DMA, we will explain the correction methods for the effect of diffusion loses and the broadening effect in the devices, and we will explain the evaluation methods of the PSL standard particles.

4IM.28

Performance of Fundamental Functional Feature on DMA (1). CHIRYO TSUNODA, *FES*

Ever since the publication of the analysis methods by Knutson and whitby (1975), differential mobility analyzer (DMA) has become most useful instrument for the research of aerosol science. However, over the past forty years, researchers in this community have not found out an accurate methods for the data analysis of DMA. To solve this longstanding issue, we have addressed the mathematical theory of the electrical mobility classification. Finally we come up with the new accurate response function which is called critically transferred response function (CTR function), if you will. CTR function are integral function and are composed by two transfer function and one distribution function of measuring objects. CTR function of DMA create two typical output data, one is linear data and the other is non-linear data. These output data are strongly related the distribution of measuring object.

Encouraged by these successful theoretical and mathematical treatment, we will explain the performances for linear output data in this first presentation. And, we will explain the typical performance for non-linear output data in the second presentation.

A Compact, Battery-Operable, Dual-Channel, Water-Based Condensation Particle Counter. SUSANNE HERING, Gregory Lewis, David Workman, *Aerosol Dynamics Inc.*

A compact, dual-channel, water-based condensation particle counter is being developed to provide simultaneous measurements of ultrafine particle concentrations in two separate flow streams. The reported parameters are the airborne number concentration of ultrafine and fine particles in each channel of the system. The size range of detected particles extends from 7 nm to several micrometers in diameter. The time resolution is 1 second. Envisioned applications encompass those requiring simultaneous measurements in multiple size fractions, or in two distinct physical spaces. The long term goal is a battery powered instrument that is wearable.

As with other condensation particle counters, this system relies on condensational enlargement to grow ultrafine particles to optically detectable sizes. Yet in contrast to those now available, the instrument being developed here provides the following advantages: (1) it uses water, rather than alcohol, for the condensational enlargement; (2) it can be operated in any orientation; (3) it tolerates tipping and jostling; (4) it detects particles as small as 7 nm in diameter and (5) it is compact.

The approach is a self-sustaining water-based condensational growth system commonly referred to as “MAGIC” (moderated aerosol growth with internal water cycling). The MAGIC technology captures water vapor internally, allowing sustained operation without need of on-board reservoirs. The growth tube of the MAGIC system has a continuous water-wetted wick that spans three temperature regions, the middle one of which is warmer than the other two. Water evaporation from the warmed, middle section provides the water vapor that creates the supersaturation for particle activation and growth. The cooler, downstream section captures this water vapor, while maintaining supersaturated conditions needed for droplet growth. Capillary action transports the water captured by this stage, and by the initial stage, back to the warmed mid-section, providing sustained operation. MAGIC has no liquid reservoirs, and thus is insensitive to orientation and motion.

For the dual-channel device presented here, two identical MAGIC growth tube channels are used, both operated at a sample air flow of 100cm^3/min. A common set of temperature controls ensures that the respective stages of each channel are operated at the same temperatures. Each growth channel is coupled to an independent optical detector which detects individual droplets to enumerate the number of concentration of condensationally enlarged particles. The optical detectors are newly developed and miniaturized to provide a compact system. The dual-channel growth tube and optics, excluding electronics and supporting components, measures approximately 6cm x 10cm x 10cm.

Laboratory evaluations have been conducted under a variety of temperature and relative humidity conditions. Testing with monodispersed aerosols has demonstrated a lower particle size limit of detection of 7nm for both sucrose and sulfate aerosols. The response is linear to the highest concentrations tested of 8x10^4/cm^3. For sampling ambient air, the standard deviation between the two channels was 2%.

Selective Collection in Particle Harvesting. MENG-DAWN CHENG, *Oak Ridge National Laboratory*

Application of magnetic collection has a long history to atmospheric source identification[1],[2],[3],[4],[5] and as the marker for indoor air pollution[6]. In fact, most elements in the periodic table and their oxide forms are paramagnetic. Thus, magnetic collection could provide an effective means of environmental sampling of aerosol particles that consist of magnetic materials. This would in essence enhance the analyte signal by selectively collect particles consisting of only relevant composition at the time of collection. To trigger selective magnetic material harvesting from airborne particulate matter, first the magnetic circuit needs to generate high-gradient magnetic field density on the order of a few Tesla (T) per meter. The recent advance in additive manufacturing of permanent magnets enable the design of such a circuit with the magnetic field density around 16 T/m, which makes selective collection of aerosol particles by their magnetic property in a small footprint and with a low-power consumption mode possible.

In this presentation, we will report the development of a particle selective collector based on a HGPMS circuit using NdFeB permanent magnets. The collector has a small footprint of the size 12”x3”x6” and ran on a battery pack. The collector built on the HGPMS principle is highly selective toward particles comprising of paramagnetic and ferromagnetic composition[7], which eliminates significant downstream effort in preparing the same for composition analysis. Results from detailed model analysis and experimental measurement on the magnetic circuit reveal the existence of localized structures in the magnetic field density distribution. Time-resolved fluorescence data show that aerosol particles were rapidly captured by the structures, not by the peripherals of the magnetic circuit. For ferromagnetic particles of 50 nm or larger in size, the HGPMS technology would collect the particles with nearly 100% efficiency. The efficiency decreases following the decrease of particle size. The harvesting efficiency of the HGPMS technology appears to be primarily dependent on the particle magnetic moment instead of particle mixing. The internal instead of external makeup of the aerosol particle population determines the separation efficiency of the HGPMS collector.

High Time Resolved Measurements of Ultrafine Particles, PM10, PM2.5, Nitric Oxides and Black Carbon at Berlin City.

MARKUS PESCH, Volker Ziegler, *Technical Director*

Although ultrafine particles account only for a little share in the total mass concentration, they are under a cloud of being harmful to health. For this reason an additional monitoring of this particle fractions´ exposure is absolutely necessary. First steps of continuous measurements of ultrafine particles have already been realized in high sophisticated systems like the Grimm EDM665 Wide Range Aerosol Spectrometer. Due to the temporal resolution of the integrated mobility spectrometer (SMPS) as well as it comparatively high costs it does not focus on area-wide monitoring of ultrafine particles.

A more competitive alternative for measuring the particle ambient exposure of ultrafine particles with high temporal resolution (1 second) is the combination of special environmental Condensation Particle Counter (CPC) in combination with a well-established Nafion drying system and an air conditioned mini-shelter. This GRIMM EDM465-UFP is absolutely qualified for continuous measurements of the ultrafine particle exposure and focus on hot- spot observations as well as on area-wide monitoring (e.g. background measurements). The device is performed for long term unattended measurements with low maintenance (1/months). Count efficiency, dryer performances and particle losses in the inlet pipe have been characterized comprehensively.

Measurements taken with the EDM465-UFP next to Berlin Zoo, Germany will be presented. The evaluation of the high time resolved data has been carried out in relation to local and regional sources and under different meteorological aspects. A condensation particle counter and a Laser spectrometer, placed at the measurement terrace of the Department of Environmental Chemistry, Technical University of Berlin, close to Berlin Zoo, is used to observe background concentration of ultrafine particles an PM values. Interesting correlations of UFP with PM10, PM2.5, NOx and black carbon will be shown.

A Method for Testing the Accuracy of the Hourly-Averaged PM2.5 Mass Concentration by Automated Measuring Systems for Continuous Monitoring with Laboratory Generated Aerosols. Yoshiko Murashima, HIROMU SAKURAI, *AIST*

We evaluated a method for testing $PM_{2.5}$ automated measuring systems for continuous monitoring ($PM_{2.5}$ systems hereafter) in the laboratory, with respect to the accuracy of the hourly-averaged mass concentration. While the accuracy of the daily-averaged mass concentration of $PM_{2.5}$ systems is tested and must be within a prescribed tolerance for qualifying for certification, there is no tolerance set for the accuracy of the hourly concentration. The accuracy of hourly concentrations is important in Japan, however, since hourly concentrations are used for issuing alerts by local governments when high $PM_{2.5}$ concentrations are expected. Testing the accuracy of hourly concentrations is not straightforward, though, since the method for testing the accuracy of daily concentrations, i.e., the comparison with the daily concentration determined by the reference filter/gravimetric method, is not applicable to hourly concentrations because of the lack of sufficient sensitivity. We propose a method for testing the accuracy of hourly concentrations that is to be performed in the laboratory, which uses laboratory-generated aerosols and a reference instrument that has a time resolution better than an hour. This method is reproducible and well-defined in comparison with methods with ambient aerosols. In this presentation, results from our experiments for validating the proposed testing method are reported.

Three types of $PM_{2.5}$ systems were tested. Two of them were beta attenuation monitors with Japanese certification (BAM-A and -B), and the other was a tapered element oscillating microbalance (TEOM). For reference measurement, we used two methods. One was a traditional filter/gravimetric method with two samplers as the primary standard, and the other was a scanning mobility particle sizer (SMPS) spectrometer as the secondary standard. The mass concentration by the SMPS was calibrated by the filter method. As test aerosols, we used two types of particles generated by the spray-drying method. One was an aerosol of 300-nm PSL spheres, and the other was a polydispersed aerosol of ammonium sulfate particles with mass mode diameter of about 120 nm. The particles were conditioned for concentration, humidity, and electrical charge, and then delivered to a manifold from which the tested $PM_{2.5}$ systems and references sampled.

We carried out two tests in the experiments. One was a test at a constant particle concentration of about 100 $\mu g/m^3$ for 3 hours. Two filter samplers gave reference 3-h average concentrations, which were compared to 3-h concentrations by the SMPS to determine correction factors for the SMPS for each particle type, i.e., PSL and ammonium sulfate. Hourly concentrations by the SMPS after correction with an appropriate correction factor thus determined were used as reference for evaluating the accuracy of hourly concentrations by the $PM_{2.5}$ systems. The agreement between the $PM_{2.5}$ systems and reference was generally good. BAM-B, however, showed large disagreements for the first hour of the 3-h measurement periods. The disagreement seemed to occur due to slow response of BAM-B. The hourly concentrations for the first hour by BAM-B seemed to be affected by the concentration before the 3-h periods, probably because the averaging time length that was set in the instrument was longer than an hour.

The other test was done at five concentration levels changed stepwise to evaluate the linearity of the $PM_{2.5}$ systems. The concentration levels were 10, 20, 40, 80, and 160 $\mu g/m^3$. Each concentration level was kept for 2 hours and the hourly concentrations of the second hour at each concentration level were compared with the hourly concentrations by the reference SMPS. The linearity was found fairly good for all of the $PM_{2.5}$ systems in the concentration range evaluated.

4IN.1

Understanding the Ice Nucleation Potential of Organic Sea Spray Aerosols. MARTIN WOLF, Lily Dove, Allison Coe, Maria Zawadowicz, Keven Dooley, Sallie Chisholm, Daniel Cziczo, *Massachusetts Institute of Technology*

The effects of atmospheric aerosols on cloud properties remain the largest source of uncertainties in predicting future climates. Processes of aerosol-induced ice nucleation affect the global radiative budget and hydrological cycle by influencing cloud formation, lifetime, albedo, and precipitation efficiency. Understanding the factors governing ice nucleation is therefore requisite to improving aerosol-cloud interactions in atmospheric models and reducing uncertainty in climate forecasts.

Atmospheric ice nucleation proceeds through processes of homogeneous and heterogeneous nucleation. In heterogeneous nucleation, an ice nucleating particle (INP) raises the temperature or lowers the ice supersaturation required to initiate ice formation. The organic components of sea spray aerosols (SSA) exhibit several qualities of effective INPs, such as such as hydrophilic functionality and the ability to increase porosity and surface roughness through glassy state phase transitions. In this study, we quantify the ice nucleation potential of laboratory generated SSA in the cirrus regime ($-60 \leq T \leq -40$ ˚C and $1.0 \leq S_{ice}$ 1.5). Nucleation potential is quantified by the temperatures and supersaturations required to initiate ice formation. NaCl and synthetic seawater were chosen as representative inorganic components of natural SSA, while aerosols generated from lysed cell cultures of the abundant and widespread phytoplankton Prochlorococcus were chosen as representative organic components of natural SSA. Deposition ice nucleation for particles generated from lysed plankton cultures initiated at ice supersaturations up to 30% lower than for purely inorganic particles, which activated in homogeneously.

We then investigated the effects of SSA composition and chemistry on nucleation. Organic enriched bubble film burst particles from lysed plankton cultures nucleated at lower ice saturations than inorganic enriched jet drop particles. We also used single component organic particles to explore the role of functionality in the nucleation of organic SSA. The deposition nucleation potential of lipids, saccharides, and proteins representative of natural marine organic matter was quantified. Lipids and oligosaccharides were overall ineffective depositional INPs, whereas polysaccharides and some amino acids were shown to mimic the effective nucleation behavior of aerosols generated from lysed cell cultures.

Finally, we present data from a recent field campaign in the Subtropical Atlantic Ocean, where Prochlorococcus is present in abundances up to 10^4 cells per mL of seawater. Organic microlayer and subsurface seawater samples were collected, aerosolized, and tested for nucleation potential in the cirrus regime.

Keywords: Sea Spray Aerosol, Ice Nucleation

4IN.2

The Influence of Dust Mineralogy on Its Aerosol Suspension Freezing Behavior. KRISTINA HÖHLER, Romy Ullrich, Thea Schiebel, Nadine Schittko, Barbara Dietel, Peter G. Weidler, Konrad Kandler, Ottmar Möhler, Thomas Leisner, *Karlsruhe Institute of Technology*

In mixed phase clouds, the freezing of individual cloud droplets is triggered by the presence of so-called ice nucleating particles (INPs). As this first ice formation usually is followed by a chain reaction of secondary ice multiplication processes, the abundance of these very rare aerosol species is critically for the initialization of precipitation and for cloud radiative properties.

Because of its high global atmospheric abundance, soil dust from arid regions is known to contribute significantly to INP concentrations, especially for freezing temperatures below -15°C. In past studies it was suggested that the immersion freezing behavior of this predominantly mineral dust can be described by a single parameterization disregarding the dust origin (Ullrich et al., 2017). On the other hand, some laboratory studies on suspension freezing behavior suggest that single mineralogical components, especially K-Feldspar, control the ice nucleating potential of the aerosols (Atkinson et al., 2013). This might imply the need for understanding the global distribution of aerosols with various compositions and the use of individual parameterizations for specific minerals in weather and cloud models.

In the INUIT09 campaign, organized at the AIDA (Aerosol Interaction and Dynamics in the Atmosphere) facility at KIT in Germany in July 2017, mineral dusts of different origin were carefully characterized according mineralogical composition and ice nucleation activity. Amongst other techniques, the new Ice Nucleation Spectrometer of the Karlsruhe Institute of Technology (INSEKT) was used to investigate the immersion freezing behavior of aerosol that was dry dispersed into a large vessel, sampled on filters and washed off. The construction of INSEKT was inspired by the design of the Colorado State University Ice Spectrometer developed by Hill et al. (2016), which enables the investigation of 50µl samples in 96-well PCR plates inserted in a temperature controlled aluminum block. INSEKT works with automated optical freezing detection during defined cooling ramps and can be used to study freezing events to temperatures as low as -27°C.

We will show first results on the immersion freezing behavior of eleven samples from different arid regions and discuss correlations with particle mineral compositions.

4IN.3

Isothermal Immersion Freezing Experiments Involving Mineral Dust: The Role of INP Surface Area. ASSAF ZIPORI, Daniel Knopf, Yinon Rudich, *Weizmann Institute of Science*

Ice nucleation in mixed phase clouds are still not well understood. This has many implications on the understanding of the radiative effects and rain formation in such clouds. Immersion freezing is considered to be the most important ice nucleation pathway in mixed-phase clouds, and recent field and modeling studies suggest a time-dependent ice nucleation process. Currently, two main approaches are used to describe immersion freezing: (1) The classical nucleation theory (CNT) that assumes a stochastic freezing process expressed by a heterogeneous ice nucleation rate coefficient (Jhet) that depends on surface area and time, and (2) a deterministic or singular (time independent) approach which is described by an ice active site density (Ns), which is determined by the surface area only.

It has been claimed that CNT fails to describe apparent varying freezing rates for isothermal experiments for single INP type. However, a recent study suggests that ice nucleation can be explained by a combination of stochastic uncertainty, when observing too little freezing events, and variation of INP surface area among droplets. We extend the experimental immersion freezing data set to test the effect of varying INP surface on immersion freezing using sufficiently large numbers of freezing events to render stochastic uncertainty negligible.

We present results of isothermal experiments using the WeIzmann Supercooled Droplets Observation on a Microchip (WISDOM). Using this setup, it is possible to analyze a large number of freezing events in each experiment, with a narrow droplet size distribution, thereby providing a good data set for analysis and parameterization. In addition, the INP efficiencies of minerals expressed as Jhet and Ns were also determined applying a constant cooling rate experiments. Those were followed by isothermal freezing experiments, where the temperature was held constant for up to three hours, for different temperatures. Jhet derived from constant cooling experiments were applied to describe the increase in the frozen fraction during the isothermal freezing experiments and for comparison with the Jhet derived directly from the isothermal freezing experiments. In the next step, the INP size distribution was examined in order to properly estimate the INP surface area distribution in the drops. By assuming a varying INP surface area distributed between the drops, the observed frozen fraction values in the isothermal freezing experiment could be described using a single value of Jhet for the applied temperature.

These experiments enhance our descriptive understanding of ice nucleation parametrization and classical nucleation theory. This will improve our ability to model primary ice nucleation in clouds for applications in cloud and climate models, with important effects on Earth’s radiation budget and the hydrological cycle.

4IN.4

Does Secondary Ice Processes in Mixed Phase Clouds More Important Than We Assume? ASSAF ZIPORI, Naama Reicher, Yigal Erel, Daniel Rosenfeld, Amir Sandler, Daniel Knopf, Yinon Rudich, *Weizmann Institute of Science*

It is generally assumed that secondary ice processes (SIP) influence the ice content in clouds that form in areas with low aerosol and ice nucleation particles (INP) concentration. However, in continental clouds, with high aerosol and INP concentrations, SIP are thought to be minor, and ice nucleation is assumed to be dominated by the INP concentration.

Here we combine field observations, laboratory measurements and model results to investigate the possible role of primary ice nucleation in continental, mixed phase, orographic clouds. Primary ice nucleation was quantified using the WeIzmann Supercooled Droplets Observation on a Microchip (WISDOM). Particles collected from rain samples were used to estimate the ice nucleation efficiency in the immersion mode. The immersion freezing results were compared with satellite-retrieved glaciation temperatures (Tg) and with an immersion freezing model, and used to examine the relative role of primary and secondary ice processes on cloud glaciation. In addition, the INP efficiency was also related to the particles' minerology.

We found that primary ice nucleation was controlled by K-Feldspar, although it was not the most abundant mineral. The role of SIP was assessed by comparing the observed Tg with the temperature where 50% of the drops froze in the WISDOM experiments (ΔT). This difference was minimal when the aerosols' concentration in the rain water was 10mg L-1. ΔT increased at lower aerosol concentration, suggesting that SIP were more effective due to larger droplets. At higher dust concentrations, ΔT increased possibly due to higher surface area available in cloud droplets compared to the WISDOM experiments. In addition, giant cloud condensation nuclei could also have initiated SIP by forming large droplets at early cloud growth stages. Using a simple model of primary ice nucleation, the calculated glaciation temperature was compared with the observed Tg. Although the model design favored primary ice nucleation, it did not explain the observed Tg from the satellite.

Our results show a direct relation between the drops size and the importance of SIP. In addition, we show that SIP is not limited to clouds with low aerosols concentration, but exist also in continental clouds, which were assumed to be less prone to SIP. This is due to large dust aerosols that are carried to the clouds during severe dust storms. These large dust aerosols can act as giant cloud condensation nuclei that freeze at relatively high temperatures, and initiate SIP. Our results emphasize the importance of SIP on Earth's radiation budget and its influence on global climate, as it is larger than usually assumed.

4IN.6

Nanoscale Ice-Nucleating Particles in Waterbodies in an Agricultural Area. HEIKE WEX, Kathryn A. Knackstedt, Bruce Moffett, Susan Hartmann, Janine Fröhlich-Nowoisky, Thomas Hill, Sarah Grawe, Robert Michael McKay, *Institute for Tropospheric Research, Germany*

Ice nucleating particles (INPs) are a neglected, but integral component of the water cycle. Abundant INPs were identified from surface waters of both the Maumee River and Lake Erie with freezing profiles spanning a temperature range tested from -30°C to -20°C. River INPs were largely attributed to biogenic macromolecules, based on their characterization showing heat denaturation of ice activity and size-fractionation of the activity using a 0.2 µm membrane. Higher concentrations of INPs were found in river samples compared to lake samples. However, the latter showed a broader increase in the freezing profile, pointing towards a different population of INPs being present in the lake.

Seasonal analysis of INPs that were ice active ≥ -10°C (INP_{-10}) showed their concentration to correlate with river discharge, suggesting a watershed origin of these INPs, a characterization supported by analysis showing similar ice nucleating signatures derived from the river and the soil fungus Mortierella alpina suggesting that fungal INPs may dominate the INP population of the river. Aerosols derived from turbulence features in the river can include INP_{-10} that may potentially influence regional weather. INP_{-10} contained within aerosols generated from a weir spanning the river ranged in concentration from 1-11 INP m^{-3} which represented a fold-change of 3.2 over average INP_{-10} concentrations sampled from aerosols at control locations.

4IN.9

Single-Particle Mixing State and Mineralogy of North African Dust: A Comparison of Ambient Transported Dust with Laboratory Generated Proxies. NICHOLAS MARSDEN, Romy Ullrich, Ottmar Möhler, Paul Williams, Michael Flynn, James Allan, Hugh Coe, *University of Manchester*

Mineral dust has been the subject of many laboratory simulations of ice nucleation (IN) due to the potential for these particles to act as ice-nucleating particles (INP). In many studies, the mineralogy of single particles has been found to influence the conditions at which ice is formed and is therefore an important parameter in this type of experiment. Furthermore, the internal mixing state, such as the coating with sulphate and organics, can alter the characteristics of INP and is also an important consideration. Therefore, the characterisation of single-particle mineralogy and mixing state of mineral dust is an important for the modelling of IN at atmospherically relevant conditions.

In this study, we present the online analysis of the fine fraction (<2.5µm) of North African dust using single-particle mass spectrometry (LAAPTOF, AeroMegt GmbH), a technique that has a unique ability to make online measurements of single-particle composition and mixing state at high temporal resolution. Using novel data evaluation methods, we evaluated the number concentrations of felsic, illite and kaolinite clay particles and the internal mixing with organic, inorganic and biological material in commonly used mineral dust proxies including; crushed microcline feldspar, synthetic illite NX, natural soil from the North-West margin of the Sahara, and natural soil from the Sahel region. The materials were sampled from the AIDA chamber, Karlsruhe Institute of Technology, prior to ice formation during the INUIT09 campaign July 2017. The data is compared to the composition of transported dust measured with the same instrument in the marine boundary layer at Praia, Republic of Cabo Verde, during the ICE-D campaign in August 2015.

The similarities and differences of the ambient dust compared to the laboratory generated proxies will be discussed with reference to the implications of dust modification during transport and the atmospheric relevance of commonly used mineral dust proxies.

4IN.10

Cleaning up Our Act: Assessment of Background Freezing Caused by Impurities and Substrates and Strategies to Reduce These Interferences in Droplet Freezing Assays.

Michael Polen, Thomas Brubaker, Josh Somers, Perry Cheng, RYAN SULLIVAN, *Carnegie Mellon University*

Droplet freezing techniques have been utilized for decades to measure the concentration of ice nucleating particles (INP) and assess the freezing properties of atmospheric particles. However, these methods suffer from contamination issues, especially in regards to impurities in the water or on the substrates used that induce freezing at temperatures warmer than the homogeneous freezing limit. Published results often do not present a sufficiently in-depth discussion of how the pure water was generated or its quality, or an assessment of background freezing due to surface interactions or matrix impurities. We present a detailed assessment of the droplet freezing temperature spectra and inferred INP concentrations obtained using different substrates in the CMU cold stage system, as well as the effects of different approaches to water purification and the resulting matrix impacts on the background freezing spectrum. We have found that bottled HPLC water along with filtration provides the lowest background signal and the most consistent pure water freezing spectra, though many in the ice nucleation community use Milli-Q generated water instead. Typical Milli-Q purification systems do not filter particles smaller than 200 nm, which could explain the inconsistent freezing spectra we observed. We have also observed the quality of the Milli-Q produced water to change suddenly with use. Substrates tested include silicon wafers, Vaseline, gold-coated surfaces, hydrophobic cover slips, and polydimethylsiloxane polymer. Our findings suggest that gold-coated substrates induce freezing at the lowest temperatures, while Vaseline consistently causes samples to freeze at higher temperatures. However, nearly all substrates induce freezing at higher temperatures than previous literature suggests, and warmer than the homogenous freezing temperature threshold. We also lay out our recommendations for future ice nucleation studies to present, in detail, how different research groups control for contamination and background freezing of a rare phenomenon that is highly sensitive to contamination. In this vein, we encourage the community to regularly publish droplet volume-normalized ice nucleating particle concentrations for pure water tests, as well as the raw droplet freezing temperature spectra. This will enable a direct comparison between methods so the community can identify the best practices and materials for droplet freezing techniques.

4IN.11

Effects of Atmospheric Chemical Aging on Biomass Burning Aerosol Composition and Ice Nucleating Properties. LYDIA JAHL, Michael Polen, Leif Jahn, Thomas Brubaker, Ryan Sullivan, *Carnegie Mellon University*

Biomass burning is a major global source of aerosol pollution that comprises nearly 80% of the total carbonaceous aerosol burden and 2700 Gg of black carbon emissions per year. The ability of some aerosol particles to nucleate ice was once thought to only occur in mineral dust and biological particles, but recent studies found that some types of biomass burning aerosol (BBA) can also nucleate ice and cause the glaciation of clouds. Cloud glaciation causes changes in the evolution of a cloud's properties and structure by initiating precipitation, influencing atmospheric chemical reactions, changing cloud lifetime and size, and altering the cloud's radiative forcing. We seek to understand what chemical properties of the aerosol particles might explain the nucleation of ice at mixed-phase cloud temperatures. Furthermore, many studies focus on the ice nucleating abilities of fresh, unaged aerosol that may not represent realistic BBA, which experiences significant chemical processing and aging. Therefore, we explored the relationships between the ice nucleating abilities and chemical properties of authentic biomass burning aerosol that we chemically aged in an environmental chamber.

We burned biomass fuels that are commonly consumed in wildfires and prescribed burns such as sawgrass, birch, and black needlerush to fill an environmental smog chamber with biomass burning aerosol smoke. The aerosol was aged using three different chemistries: hydroxyl radical aging by injection of nitrous acid with UV lights, dark ozonolysis, and by hydroxyl radical aging of aerosol particle surfaces only by first passing the aerosol through a thermal denuder to remove organic components. In several systems, hydroxyl radical aging was found to enhance the aerosol's ice nucleation properties. For example, the ice active site density of cutgrass BBA increased by half an order of magnitude following oxidation corresponding to a 10% increase in the O:C ratio of the aerosol. However, this was not an effect consistently observed for all biomass fuels tested. The chemical composition of the aerosol was analyzed using two single-particle mass spectrometers (SP-AMS and LAAPTOF), and the particles were collected on filters for SEM/EDX analysis and to determine their ice nucleating abilities. We analyzed the ice nucleating properties of the biomass burning aerosol on a cold plate using two different droplet generation techniques: droplets directly pipetted into an oil bath and droplets stored and created on a custom microfluidic chip. We will present our findings on the changes in the aerosol's composition following chemical aging, and will correlate the ice nucleating abilities of different plant species' fresh and aged emissions to their aerosol chemical composition.

4IN.12

Responses of Mixed-Phase Cloud Condensates and Cloud Radiative Effects to Ice Nucleating Particle Distributions in DOE E3SM model.

YANG SHI, Xiaohong Liu, Mingxuan Wu, Kai Zhang, *University of Wyoming*

Mixed-phase clouds frequently observed in the Arctic and mid-latitude storm tracks have substantial impacts on the global energy budget, precipitation, and climate. In this study, we first implement two empirical ice nucleation parameterizations (Niemand et al. 2012 and DeMott et al. 2015) in the DOE Energy Exascale Earth System Model version 1 and version 0 (E3SM v1 and v0). For both of the two model versions, model simulated ice nucleating particle (INP) concentrations using Niemand et al. and DeMott et al. are compared with the simulation using default classical-nucleation-theory-based ice nucleation scheme (CNT). We find that Niemand et al. presents significantly higher (a factor of 3) INP concentrations than DeMott et al. and CNT near the dust source regions. Moreover, because of the more efficient aerosol (dust) transport to the Polar Regions, E3SM v1 shows around 100 times more INP than E3SM v0 at the Arctic regions for all of the three parameterizations. This also causes a 20% difference in liquid water path and a 10% difference in cloud radiative forcing (shortwave and longwave) in the Arctic regions between the three ice nucleation shcemes in E3SM v1, which are not seen in E3SM v0. Finally, the dust burdens from E3SM v1 and v0 are compared with CALIPSO data and the surface observation at the Alert station in Canada.

Activation of Intact Bacteria and Bacterial Fragments Mixed with Agar as Cloud Droplets and Ice Crystals in Cloud Chamber Experiments. KAITLYN J. SUSKI, David Bell, Naruki Hiranuma, Ottmar Möhler, Dan Imre, Alla Zelenyuk, *Pacific Northwest National Laboratory*

Bacteria has been extensively studied for its ability to nucleate ice in the immersion regime at modestly supercooled temperatures. Previous studies have shown that while whole bacteria cells are efficient ice nucleating particles (INPs), smaller bacterial fragments and even individual proteins from bacteria can also serve as INPs. Experiments conducted at the Aerosol Interaction and Dynamics in the Atmosphere (AIDA) cloud chamber at the Karlsruhe Institute of Technology (KIT) investigated the ice nucleation activity of two strains of cultivated bacteria (pseudomonas syringae and PF CGina) by forming a cloud via expansion at temperatures between -5 and -12 °C. We find that bacterial fragments mixed with agar growth media activate as cloud condensation nuclei (CCN) and INPs, while intact bacteria cells were not observed in cloud droplet and ice crystal residuals.

Cloud droplet residuals were sampled using a pumped counterflow virtual impactor inlet (PCVI) and ice crystal residuals were sampled using an ice-selecting PCVI (IS-PCVI). A single particle mass spectrometer (miniSPLAT) was used to characterize the size and chemistry of aerosol particles and cloud residuals. The aerosol in the AIDA chamber before and after the expansions had a bimodal size distribution with agar mixed with bacterial fragments comprising the smaller size mode and whole bacteria cells making up the larger size mode. Three expansions were performed with two bacteria strains and all expansions showed that the cloud droplet residuals had the same size distribution and mass spectral signatures of the bacteria fragments mixed with agar. Additionally, the ice crystal residuals were also composed of bacteria fragments mixed with agar. Due to the fact that an immersion mode INP must first become incorporated into a cloud droplet, whole bacteria cells were unable to serve as INPs in these experiments due to their limited CCN activity.

Previous studies have suggested that bacteria can range from hydrophobic to slightly hydrophilic due to the varying makeup of the bacteria cell wall. Thus, if bacteria are not hygroscopic, it could explain why they are less CCN active than bacteria fragments that are not completely enveloped in a cell wall and are mixed with a very hygroscopic material, in this case agar. These results suggest that in clouds where water vapor is limited, competition for water vapor between weakly hygroscopic intact bacteria and other more hygroscopic particles could result in a negligible amount of intact bacteria serving as CCN and INP in the immersion mode. In the laboratory, bulk immersion freezing measurements do not capture this competition for water vapor as particles are submerged in a well of water or a water droplet artificially overcoming this barrier to CCN activation. Also, if agar is adding to the hygroscopicity of the bacteria fragments in cultivated bacteria and enhancing their CCN and thus immersion INP activity, the role of agar must be quantified to understand these laboratory data in relation to real clouds.

Ice Nucleation Activity of Glassy Soil Organic Particles under Cirrus Conditions. SWARUP CHINA, Daniel Veghte, Joseph Charnawskas, Johannes Weis, Kaitlyn J. Suski, Gourihar Kulkarni, Bingbing Wang, Peng Lin, Alla Zelenyuk, Mary Gilles, Daniel Knopf, Alexander Laskin, *Pacific Northwest National Laboratory*

Glassy soil organic particles can play a significant role in heterogeneous ice nucleation under cirrus cloud conditions. Our previous study showed formation of airborne soil organic particles (ASOP) from the soil surface after intensive rain events in the Southern Great Plains (SGP), Oklahoma. In this study we collected aliquots of 'soil organic matter brine' from a puddle created by the rain events to generate spherical solid ASOP-like particles under laboratory conditions. Chemical imaging and micro-spectroscopy analysis of soil organic particles are performed to characterize their physico-chemical properties. Furthermore, molecular characterization and elemental composition analysis of particle constituents are performed by high-resolution mass spectrometry. We utilize a custom-built ice nucleation cell, interfaced with an Environmental Scanning Electron Microscope (IN-ESEM platform) operated at temperature and relative humidity relevant for cirrus cloud formation to investigate ice nucleation propensity of these laboratory generated soil organic particles. We show dynamic microscopic observations of ice nucleation events on individual submicron size soil organic particles via deposition mode. Our results show that relative humidity with respect to ice of soil organic particles is similar for to that of Suwannee River Fulvic Acid particles. Overall, our results show that soil organic particles promote ice formation under cirrus conditions.

4IN.15

Chemistry of Ice Nucleating Particles in Summertime Urban/Marine Conditions. MARIA ZAWADOWICZ, Michael Roesch, Martin Wolf, Daniel Cziczo, *Massachusetts Institute of Technology*

Formation of ice in the atmosphere depends critically on the availability of ice nucleating particles (INPs). Field and laboratory measurements indicate that a small fraction of tropospheric aerosol particles are efficient INPs and that their chemistry is distinct from that of bulk aerosol. Although the specific chemical qualities that govern ice nucleation efficiency remain uncertain, mineral dust, metallic anthropogenic particles and certain species of bioaerosol have been shown to be efficient INPs in field and laboratory studies. In this experiment, a single particle mass spectrometer (Particle Analysis by Laser Mass Spectrometry, PALMS) was coupled to a continuous flow diffusion chamber (Spectrometer for Ice Nuclei, SPIN) using a pumped counterflow virtual impactor (PCVI). The resulting instrument combination allows direct measurement of ambient INPs under a range of temperature and saturation conditions and simultaneous characterization of chemical composition of their residuals. The technique was validated in the laboratory and deployed in downtown Cambridge, MA to sample air masses of continental and marine origin, strongly influenced by Boston-area pollution. Temperature and saturation conditions consistent with deposition and immersion ice nucleation modes were used.

4IN.16

Effect of Solutes on Ice Nucleation Efficiency of Feldspar. JINGWEI YUN, Jon Davidson, Allan Bertram, *University of British Columbia*

Mineral dust particles are abundant in the atmosphere. When these particles are immersed in cloud droplets they can catalyze the nucleation of the ice phase. One type of mineral dust particle that is especially good at nucleating the ice phase is microcline (a potassium-rich feldspar) (Atkinson et al., 2013). When mineral dust particles are immersed in cloud droplets, organic and inorganic solutes are typically present. Our work focuses on the effect of these organic and inorganic solutes on the freezing properties of microcline immersed in droplets. Experiments were carried out with the droplet freezing technique as described in Whale et al. (2015). A range of organic and inorganic solutes was studied including a series of inorganic nitrates. The results show that the studied solutes have a larger effect on the freezing properties of microcline than expected from freezing point depression caused by solutes. Results from these studies will be presented and discussed.

4IN.18

Effect of Surface Geometry on Heterogeneous Ice Nucleation. Olli Pakarinen, Golnaz Roudsari, EVGENI ZAPADINSKY, Hanna Vehkamäki, *University of Helsinki*

Understanding the way in which ice forms is of great importance to many fields of science. Pure water droplets in the atmosphere can remain unfrozen to nearly -40º C. Crystallization of ice in the atmosphere therefore typically occurs in the presence of aerosol particles, such as mineral dust, soot or organic particles. These ice nucleating particles (INPs) cause heterogeneous ice nucleation at clearly higher temperatures than possible through homogeneous ice nucleation. Therefore, a better understanding of how the various types of aerosol particles present in the atmosphere affect ice nucleation (IN) in clouds would improve our ability to measure, model and parameterize the key processes related to ice- and mixed-phase cloud formation, and would advance the field of atmospheric science.

Experiments have shown in great detail what is the IN activity of different types of compounds, and recently also clarified the importance of small surface features such as surface defects. The molecular-scale processes responsible for ice nucleation are still not well known, however, and difficulties in atomic-scale characterization of complex and imperfect surfaces means that a full understanding of these processes from solely experimental evidence is still a distant goal. In recent years, several computational studies have been published on heterogeneous ice nucleation, advancing our understanding of the details of ice nucleation in many materials. The role of defects has been studied less, but recently the importance of feldspar microstructure and different crystallographic faces of feldspar were shown to be responsible for IN activity of feldspars (Kiselev et al., 2017). Simulations also showed enhanced ice nucleation efficiency in confined geometry such as wedges or pits (Bi, Cao and Li, 2017).

We are studying these topics by utilizing the monatomic water model (Molinero and Moore, 2009) for unbiased molecular dynamics (MD) simulations, where a system including a defected surface, such as pyramidal pits, steps or surface cracks, immersed in water, is cooled continuously below the melting point over tens of nanoseconds of simulation time and crystallization is followed.

Results of simulations on pyramidal pits on Si (100) surfaces, for example, show a clear ($\Delta T > 10$º C) enhancement of ice nucleation compared to flat Si (100) or Si (111) surfaces. Understanding the enhanced activity in such confined geometry may lead to characterization of active sites on some ice nucleating materials, as well as to development of optimal cloud seeding materials.

Adsorption Nucleation Theory for Ice Formation from the Vapour Phase. ANDRÉ WELTI, Ana A. Piedehierro, Yrjö Viisanen, Annele Virtanen, Lise Deschutter, Outi Meinander, Ari Laaksonen, *Finnish Meteorological Institute*

The recently developed framework of adsorption nucleation is applied to describe ice formation from the vapour phase on insoluble particles. The theory (Laaksonen, 2015; Laaksonen and Malila, 2016) is based on a combination of the Frenkel-Halsey-Hill (FHH) adsorption isotherm and the Kelvin equation, and it describes the adsorption of water in spherical clusters on a substrate and predicts, in dependence of substrate properties the critical saturation at which clusters reach a stable size. These ice clusters then serve as centres for ice to grow into a macroscopic ice crystal. The theory has previously been applied successfully to predict onset conditions of ice nucleation triggered by several soot species at low temperatures (Laaksonen et al., 2018).

Here we investigate if the theory works equally well for ice formation on natural mineral dust samples including Arizona Test Dust and Islandic dust of volcanic origin. Input parameters for the adsorption nucleation theory (contact angle and FHH adsorption parameters between water and the substrate) are determined experimentally for the same samples the ice nucleation efficiency has been measured.
The theoretical predictions of the adsorption nucleation framework and of classical nucleation theory are contrasted with measurements from the literature, so that the comparison serves as a test of correctness of the theories.

A Microfluidic Ice Nucleating Particle Counter for Continuous Measurements. Ali Mohammadi Nafchi, Gavin McMeeking, ANDREW METCALF, *Clemson University*

Droplet freezing experiments have been of interest for many years because of the difficulty in describing ice formation in the atmosphere with a single theoretical model. The majority of these experiments are conducted in a chamber or flow tube on a population of particles to determine parameters necessary for modeling ice nucleation in the atmosphere. Recent advancements can examine freeze-thaw cycles in single droplets on a microscope cold stage using oil immersion techniques. The techniques currently employed by the community are typically only capable of batch measurements, and the sum of many measurements represents the behavior of a population of ice nucleating particles.

In this talk, we present a new technique to provide continuous measurements of droplet freezing and thawing events, with the ultimate goal of continuously counting ice nucleating particles (INP). Droplet microfluidics are combined with on-chip temperature measurements and a multi-zone cold stage to continuously generate, freeze, and thaw liquid droplets. Temperature control to at least -40 degrees C will allow homogeneous freezing of pure water droplets with rapid repeatability. The microfluidic device includes an embedded platinum resistance temperature detector array which precisely measures temperature at 19 points along the fluid flow channel. The microfluidic device sits on a temperature control block which has 7 discrete temperature zones capable of causing a temperature gradient along the fluid flow. Multiple temperature zones allow hot-cold-hot hysteresis cycles to be observed in single droplets. Initial experiments with this new platform include high-speed observations of droplet freezing at a range of temperatures and INP concentrations.

Probing the Identity of the Ice Nucleating Particles (INPs) in a Boreal Environment. MIKHAIL PARAMONOV, Saskia Drossaart van Dusseldorp, Zamin Abdulali Kanji, *ETH Zürich*

Ice nucleation is an important pathway for cloud formation and initiation of precipitation in the atmosphere, thus affecting the Earth's hydrological cycle, energy and radiative balance (Mülmenstädt et al., 2015). It has been shown that a significant fraction of precipitating clouds in various environments contains ice, e.g. both in the tropics (Lau and Wu, 2003) and in the Nordic countries (Sporre et al., 2014). However, in many cases, the exact identity of an ice nucleating particle (INP) in a particular environment, as well as the properties that make an atmospheric INP an efficient one are still not fully understood (Kanji et al., 2017).

A ubiquitous aerosol particle species, the effect of which on atmospheric ice nucleation has not been thoroughly investigated, is the secondary organic aerosol (SOA). Boreal forest, which covers approximately 8% of the world's land area, is a significant source of SOA in the atmosphere. Therefore, an intensive measurement campaign, HyIce2018, is planned at the SMEAR II (Station for Measuring Ecosystem-Atmosphere Relations) boreal site in Hyytiälä Forestry Field Station in southern Finland (Hari and Kulmala, 2005). The measurement campaign is an international collaborative effort, involving several research institutions and various ice nucleation measurement techniques, supplemented by aircraft and tethered balloon, as well as the comprehensive network of aerosol- and meteorology-related continuous measurements deployed at the site. ETH Zürich will participate in the campaign in February-March of 2018 for approximately six weeks.

Continuous ice nucleation measurements will be conducted by the Portable Ice Nucleation Chamber (PINC) at a temperature of 242K in condensation freezing mode (i.e. above water saturation). The expectedly low INP concentrations at the site will be enhanced by a powerful aerosol particle concentrator, which can increase the particle number concentration by as much as a factor of 25. Besides INP number concentrations measured by PINC, the chemical composition of INP will be deduced from mass spectrometry, as well as from measurements of biomass burning and biological fluorescent particles. The participation of several research groups will also allow for an intercomparison of the deployed ice nucleation measurement techniques.

HyIce2018 is expected to be the first measurement campaign aiming at quantifying and qualifying the ambient INPs in a boreal environment. The planned measurement activities are expected to shed light on the identity of the INPs and the effect of SOA, biomass burning and biogenic aerosol particles on atmospheric ice nucleation.

Hyperthermic Intracavitary Nanoaerosol Therapy (HINAT) - a Promising Approach to Treat Peritonealcarcinomatosis.

Daniel Göhler, Stephan Große, LARS HILLEMANN, Alexander Bellendorf, Thomas A. Falkenstein, Mehdi Ouaissi, Jürgen Zieren, Michael Stintz, Urs Giger-Pabst, *Technische Universität Dresden*

Pressurized Intraperitoneal Aerosol Chemotherapy (PIPAC) is an upcoming approach for the treatment of end-stage patients suffering on advanced peritonealcarcinomatosis. During conventional PIPAC (cPIPAC), a chemotherapeutic solution is aerosolized by a single-fluid nozzle (called micro injection pump MIP$^{®}$) within the capnoperitoneum (i.e., inflated peritoneum with an overpressure of 1.6 kPa = 12 mmHg based on carbon dioxide). This kind of drug delivery (Solaß et al. 2012) circumvents several problems (e.g. adverse effects, systemic intolerance, ineffective drug delivery) accompanied to other established therapeutic methods (e.g. intraperitoneal resection, systemic chemotherapy or intraperitoneal liquid chemotherapy). But recently performed granulometric analyses on the aerosol of cPIPAC revealed a high optimization potential (Göhler et al. 2017a).

Thus a new PIPAC method (Göhler et al. 2017b), called Hyperthermic IntraCavitary NanoAerosol Therapy (HINAT), was developed to improve the homogeneity as well as the effectivity of drug deposition over the whole peritoneum. HINAT provides a nanometer-sized, unipolar-charged and hyperthermic aerosol for intracavitary use based on extracavitary aerosol generation (i.e. atomization by a two-fluid nozzle and immediate separation of coarse droplets) with subsequent aerosol conditioning.

The performance of both HINAT and cPIPAC were characterized in a comprehensive testing program, which comprised ex vivo granulometric analyses (laser diffraction spectrometry, time of flight spectrometry, differential electrical mobility analyses, condensation nuclei counting) for aerosol characterization, in post mortem swine analyses (scintigraphic peritoneography, fluorescence microscopy) for the characterization of spatial drug distribution and in-tissue drug penetration and in vivo proof of concept analyses in anesthetized swines.

Results show, that HINAT provides despite a hundreds times lower liquid drug flow rate a 25 times higher droplet generation rate than cPIPAC with a quasi-uniform deposition profile over the whole peritoneum. At a 3 times lower dose of a chemotherapeutic substance, the drug penetration depth of HINAT was found to be two times higher than the one for cPIPAC. Further information on the HINAT method and even more detailed results will be presented.

Analysis of Xenon Mass Transfer from Human Upper Airway to Systemic Regions using a Hybrid CFD-PBPK Model.

AHMADREZA HAGHNEGAHDAR, Jianan Zhao, Max Kozak, Patrick Williamson, Yu Feng, *Oklahoma State University, Stillwater, OK, USA*

Administrating incorrect doses of conventional anesthetic agents through the pulmonary route can cause potential health risks such as blood coagulation, platelet dysfunction, and deteriorating organ function. As an alternative, Xenon induces negligible impact on the cardiovascular system and also provide a neuroprotective effect, hemodynamic stability, and fast recovery. However, the inhalation still needs to be carefully monitored and controlled to avoid health risks caused by overdosing patients in unconsciousness. Thus, high-resolution lung absorption and whole-body translocation data are in critical need to fully understand how to administrate the gas via inhalation and coordinate with the patient to accurately control the dose. Clinical studies are not able to provide accurate dosimetry data due to their limited operational flexibility and imaging resolution. Therefore, a Computational Fluid Dynamics (CFD) model was employed in this study to simulate the transport and absorption of the inhaled Xenon which is connected with a Physiologically Based Pharmacokinetic (PBPK) model to predict the translocation into the systemic regions. To study the effects of different breathing patterns on Xenon transport dynamics and the concentration within the plasma and important organs, two inhalation durations (2 sec and 1.5 sec) were selected for each breathing cycle. Averaged inhalation flow rate is fixed at 3L/min to represent adults at rest. As this study only simulate inspiratory phase, a 1-sec holding time was applied to represent the expiratory phase. Simulations were performed in a subject-specific human upper airway configuration from mouth to G6. Our numerical results show that with the accurate lung uptake predictions obtained from the CFD model, the hybrid CFD-PBPK model generates more precise trends compared to simple PBPK models. In both cases, the concentrations increase with time before reaching a plateau after about 20 minutes. For 2-sec and 1.5 sec inhalation durations, the maximum values of Xenon uptake concentration during one single inhalation are approximately 0.1 and 0.07 mol/L respectively. The comparison indicates that higher uptake concentration of Xenon occurs with the long inhalation duration. Furthermore, the parametric analysis indicates that the plasma concentration of Xenon is significantly higher with the long inhalation duration. In conclusion, breathing pattern can significantly influence the Xenon uptake in the human body, which can be utilized as a critical factor to be coordinated by clinicians to achieve the optimized Xenon dose.

Aerosol Based Nanoscale Material Synthesis, Surface Engineering and Delivery to the Brain. RAMESH RALIYA, Nathan Reed, Debajit Saha, Dezhuang Ye, Tandeep Chadha, Hong Chen, Barani Raman, Pratim Biswas, *Washington University in St. Louis*

The brain is shielded by a group of parenchyma cells connected by tight junctions to protect the organ from foreign substances. The protecting layer of these cells, known as blood-brain barrier (BBB), creates an obstacle to the delivery and translocation of drugs to the brain. Current practices such as invasive delivery or non-invasive nasal droplet are limited either by a high risk of brain damage or slow and low volume delivery. In this study, we investigate a non-invasive approach, generating an aerosol suspension of ultra-small particles that can be delivered to the brain relatively faster than current medical practices. We used aerosol atomizers such as electrospray and Collison nebulizers to generate particles in the size range between 5 and 150 nm while maintaining particle properties and its uniform size distribution. The real-time particle size was measured by scanning mobility particle sizers. We have successfully tested the delivery of 5 nm gold particles to the locust brain and quantified particle delivery/uptake in the brain using inductively coupled plasma-mass spectroscopy. Building on this work, focused ultrasound technology is used for enhanced targeted delivery of nanoscale materials in the brain, potentially for brain cancer treatment. Such particles can be used as drug delivery vehicles, however, this would require a detailed investigation into the transport and delivery mechanism.

4MD.4

Pores of Kohn: Forgotten Alveolar Structures and Potential Aerosol Generators? MICHAEL OLDHAM, Owen Moss, *Altria Client Services LLC*

Analysis of aerosols in human and animal exhaled breath has identified numerous compounds from the deep lung, including proteins and surfactant constituents. Some mechanisms like coughing or surfactant/mucus plugs have been proposed to explain the presence of these exhaled deep lung constituents. However, these proposed mechanisms do not explain their presence, during normal breathing. Furthermore, current deterministic and computational fluid dynamic models do not provide insight into the means of generating such aerosols. This work explores the possibility that deep lung aerosols might be generated as a normal function of the opening of pores of Kohn.

Pores of Kohn are between-alveoli channels that have been found in numerous species including humans. Initially, pores of Kohn were thought to provide collateral ventilation to prevent excessive localized alveolar pressure. However, currently they are thought to provide collateral ventilation only under extreme conditions of alveolar duct or terminal bronchiole blockage. Additionally the pores are hypothesized to be fluid filled connections between alveoli, reservoirs for surfactant, portals for macrophage movement, and structures that are initially damaged (during development of emphysema when individual alveoli erode and seem to merge) in empheysema.

We reconsider a possible mechanism by which the pores of Kohn might open under normal breathing conditions. During inhalation alveolar tissue stretches, causing pore diameter to increase in spite of resistance from the surface tension of fluid filling the pore. Pore diameter continues to slowly increase until the meniscus at either end of the pore touch thus forming a thin unstable film. When this film randomly breaks during inspiration, the fluid surface tension now contributes to pore expansion. Furthermore, when the fluid film breaks an aerosol is formed.

The instability in the surfactant film, due to change in diameter of a pore of Kohn, results in opening of the pore following breakage of the film -- which can generate aerosols containing surfactant constituents. To more accurately calculate lung deposition and aerosol generation, pores of Kohn should be integrated into deterministic and computational fluid dynamic models.

4MD.5

Characterization of Airspace Dimension Assessment with Nanoparticles (AiDA) on a Large Population and Relation to Anthropometry and Lung Function Parameters. JONAS JAKOBSSON, H Laura Aaltonen, Hanna Nicklasson, Sandra Diaz, Per Wollmer, Jakob Löndahl, *Lund University*

Introduction

Airspace Dimension Assessment (AiDA) is a technique to assess airspace dimensions in the distal lung by measuring the recovery of inhaled nanoparticles (Löndahl et al. 2016, Jakobsson et al. 2016). It has previously been shown that the average diffusion distances, corresponding to effective airspace dimensions, can be inferred by measuring the half-life time of inhaled nanoparticles (Löndahl et al. 2016). It has also been suggested that estimated particle recovery after a hypothetical measurement without breath-hold (called the intercept) may hold additional information about individual lung features related to the conducting airways.

The aim of this work was to investigate the characteristics of the AiDA technique and the relation of the AiDA parameters to anthropometry and lung function parameters in a large population of mostly healthy subjects.

Method

Nineteen healthy subjects performed measurements of recovery of inhaled nanoparticles for breath-holding times between 5 and 20 s and volumetric sample depths between approx. 200 and 5000 mL. A simplified protocol, measuring recovery at a fixed (1300 mL) sample depth and breath-holding times between 5 and 10 s was performed by a larger group (n = 668). The measurements were performed with monodisperse 50 nm polystyrene nanospheres.

All subjects underwent a detailed investigation of lung function, including measurement of vital capacity (VC), forced expiratory volume in 1 s (FEV_1), lung diffusing capacity for carbon monoxide ($D_{L,CO}$) and forced oscillation technique (FOT), which gives information about respiratory resistance and reactance. The larger group also underwent a computed tomography (CT) scan of the lungs, to detect and quantify respiratory disease.

Characteristics of the derived airspace dimensions and the intercept (zero breath-hold recovery) were analysed in detail for the smaller group. Statistical analysis comparing AiDA to anthropometry and clinical lung function parameters was performed for the larger group to elucidate the AiDA parameters relation to established clinical techniques.

Results

The data from the smaller group showed that the derived airspace dimensions showed reasonable agreement with lung models based on histological measurements. The dimensions are root mean square (RMS) diameters of the airspaces and therefore larger than a normal arithmetic mean. The data also showed that both the airspace dimension and intercept were highly reproducible with sufficient sensitivity to reflect individual lung morphology.

The statistical analysis showed that the airspace dimensions correlated mainly with age, $D_{L,CO}$ and FEV_1/VC while the intercept correlated mainly with height, VC, FEV_1 and FOT. Importantly, airspace dimensions and intercept did not correlate strongly (n.s. for n = 19), (p =.02, r = -.09 for n = 668). Significant differences were detected between smokers (n = 101) and non-smokers (n = 570) ($p < 0.00011$ for intercept, $p < 0.0068$ for airspace dimensions) and between subjects with emphysema (n = 58, assessed with CT) and healthy subjects (n = 604), ($p < 0.0023$, $p < 0.0000000002$) for intercept and airspace dimensions, respectively.

Conclusion

The results show that the AiDA-derived airspace dimension and intercept convey independent information about individual lung properties. They further suggest that AiDA may have sensitivity to lung abnormalities (such as caused by smoking and respiratory disease); however studies including more subjects with respiratory disease are needed to evaluate the clinical value of the technique.

Predicting Local and Systemic Distributions of Inhaled Budesonide Powders using In Vitro Experiments Combined with Numerical Modeling. CONOR A. RUZYCKI, Brynn Murphy, Hafeez Nathoo, Warren H. Finlay, Andrew R. Martin, *University of Alberta*

Modeling regional deposition of inhaled pharmaceutical aerosols in the respiratory tract provides useful information with which to assess dosing to targeted airways or lung regions. For single breath inhalers such as dry powder inhalers (DPIs) or pressurized metered-dose inhalers (pMDIs), the physics governing aerosol generation and deposition in the mouth and throat is complex, and difficult to capture with existing mathematical models. As such, for these inhalers it is common to estimate extrathoracic deposition experimentally, using idealized or realistic mouth-throat geometries. The size distribution of aerosol penetrating these geometries can then be measured, and used as input to models used to predict regional deposition through the lower airways of the lung.

Recently, predictions of regional deposition fractions have been coupled with models of dispersion, incorporating drug particle dissolution, mucociliary clearance, and absorption, in order to predict the duration of local and systemic exposure to inhaled drugs following aerosol delivery. Such predictions are valuable in assessing whether and for how long therapeutic drug concentrations are achieved in targeted lung regions, and in comparing relative exposures between alternative devices or formulations used to administer the same drug.

In the present work, we examined local and systemic drug concentrations over time following inhalation of budesonide from three different commercial DPIs. Extrathoracic deposition was measured *in vitro* using the Alberta Idealized Throat (AIT). Particle size distributions penetrating the AIT were measured using a Next Generation Impactor (NGI). The mass of drug captured by the AIT, and on each stage of the NGI, served as input to a regional deposition model used to predict deposited undissolved drug mass in each generation of the lung. Subsequent dissolution of drug in the airway surface liquid (ASL) was modeled as a Nernst-Brunner process. The ASL concentrations of dissolved drug in each airway generation, as well as systemic drug concentrations, were then predicted using a recently-developed compartmental disposition model, incorporating first-order rate constants to describe the competing processes of drug clearance and absorption from the lungs.

Predictions of local and systemic budesonide exposure will be presented and compared for the three DPIs studied. In addition, predicted concentrations of dissolved drug in the ASL will be discussed in relation to *in vitro* and pharmacokinetic metrics currently used to evaluate equivalency between inhalers.

Protein Aggregation Kinetics by Electrospray Differential Mobility Analysis. KALEB DUELGE, Vince Hackley, Michael Zachariah, *University of Maryland, College Park*

Protein aggregation is an important concern in protein therapeutics, resulting in adverse immunological response in patients. New therapeutics seeking FDA approval require some form of an induced aggregation study to indicate the stability of the formulation. Techniques to investigate aggregation include: fluorescence, analytical ultracentrifugation and light scattering with or without an initial separation step. Size exclusion chromatography and field flow fractionation separate the protein particles by size in solution and then detect the particles using light absorbance or scattering. These techniques allow for the calculation of aggregation kinetics by monitoring the loss of the protein monomer with time. We present results on the use of Electrospray Differential Mobility Analysis (ES-DMA) as an alternative means to study protein aggregation. ES-DMA is used to determine the temporal distribution of monomer, dimer and higher aggregates. These results are used to determine rate laws and rate constants under various thermal and buffer conditions. Comparison to more traditional methods will be examined.

4MD.8

Characterization of the Aerosol Flow, Sampling and Deposition in a Nose Only Exposure Chamber. FRANCESCO LUCCI, Wei Teck Tan, Subash Krishnan, Julia Hoeng, Patrick Vanscheeuwijck, Rudolph Jaeger, Arkadiusz Kuczaj, *Philip Morris International R&D*

For in vivo drug delivery or toxicological assessment, a variety of inhalation exposure chambers may be employed. In particular, rodent exposure in mice requires efficient and targeted exposure systems. The Nose Only Exposure Chamber (NOEC) produced by CH Technologies (USA) meets this need and simultaneously conveys aerosols to separated breathing ports. This feature limits other non-respiratory aerosol absorption paths that may complicate biological response analyses and it also minimizes the amount of test aerosol that is required for the exposure.

Any exposure system introduces a certain variability in the aerosol exposure caused either by the system design and functioning principles and/or limited influence to control behavior of the rodents. In our tailored NOEC system, the aerosol mixture flows vertically downward through an inner plenum and the aerosol is distributed horizontally through 60 exposure ports. These are staggered at 15 degree offsets between 5 adjoining tiers of 12 ports each. Ports are loaded with air tight glass tubes to separately host and position the mice. The aerosol is exhausted through an outer plenum peripheral to the inner plenum. A uniform aerosol delivery between all ports is desired for reliable performance of the exposure studies. The aim of the present analysis is to investigate aerosol flow characteristics in the NOEC system and estimate any potential size-dependent (> 1 mum) aerosol sampling non-uniformities at the mouse port. Such insight generally should lead to better understanding of the operating conditions during exposure and further optimization of the system.

For the investigations we have employed experimental and computational techniques. In particular, operating flow conditions and user-requirements concerning aerosol measurement devices make the acquisition of the experimental data very challenging. The novelty of our approach is the application of our recently developed Eulerian Computational Fluid Dynamics solver (AeroSolved: www.aerosolved.com) designed to simulate polydisperse multi-species aerosol transport and deposition. The aerosol equations include drag, gravitational and Brownian diffusion forces. We investigated aerosol transport and sampling through the main components of the system under actual operating conditions, obtaining unique verification data. Available experimental data concerning the flow were used to verify the computed results.

Computational results show that under operating condition, the central jet delivering the aerosol to the inner plenum produces a recirculation zone between the middle and the upper part of the plenum. The resulting pressure variations will cause a maximum flow variability of 20% at the ports, a result consistent with the acquired experimental data. Flow uniformity inside the plenum can be controlled by the adjustment of the aerosol delivery inlet diameter. Assuming operational flow rate at the port of and realistic in the average value inhalation flow rate to the closed by the mouse nose exposure tube, we have identified a small (<1%) preferential aerosol flux sampling to the nose port due to the aerosol drift from the flow streamlines near to the port. Detailed computational investigations will be presented along with the experimental verification of the system functioning for various aerosol flows.

Method for the Production of "Universal" Inhalation Powders for Dry Powder Inhalers. Janne Raula, DAVID BROWN, Esko Kauppinen, *Teicos Pharma*

Teicos Pharma has developed a unique inhalation drug formulation technology (trade named "Particle Stream Technology") which allows the production of highly flowable and dispersible inhalation powders (trade named "ProFlow Powder") from virtually any pharmaceutical agent and at low cost. This technology enables the production of highly efficient and fast acting inhalable "carrier free" formulations of wide range of active pharmaceutical ingredients (APIs), be they water soluable or insoluable, for pulmonary or systemic disease. The formulation also provides patients a painless and effective dosing procedure which avoids the side effects of traditional carrier containing inhalation formulations.

Carrier free formulations have been demonstrated to have a up to 99% API, compared to 1-2% API in traditional milled powders, Fine Particle Fractions (FPFs) above 55% compared to 10-15% in traditional milled powders and emitted doses of over 20x traditional milled formulations. In combination formulations including lactose carrier particles, we have achieved FPFs of greater than 90%. Emited doses have been demonstrated to be virtually independent of inhalation flow rate in the normal human inhalation range of 22 to 55 LPM. In-vitro tests have demonstrated safe biocompatablity.

4MD.10

Investigation of Single Particle Frictional Electrification with Polymer Plate. JIAWEI HU, Cai Liang, Lunbo Duan, Xiaoping Chen, Daoyin Liu, Changsui Zhao, *School of Energy and Environment, Southeast University*

In Dry Power Inhalers, the small drug particulates are always highly charged due to continuously contact with the device and other particles. The accumulation of static charges on drug particles may lead to particle- device adhesion which significantly affects drug delivery, drug disposal, and dosage in DPIs. In order to explore the mechanism of electrostatic charging in DPIs, a simplifying approach by investigating the triboelectrification of a single particle sliding on a polymer plate has been conducted in this work. To obtain the accuracy triboelectric charge due to sliding, the initial charge on the particle before sliding and the final charge after the particle separate from the plate were measured with two Faraday Cups. The results indicated that the final charge of the particle was found to be linear with the initial charge for a short sliding distance, whereas the experimental data became scattered for a long sliding length. The influences of the sliding length and normal load on the triboelectric charge density were analyzed by considering the contact area. Furthermore, the triboelectric charge density was able to be fundamentally described as a function of the sliding contact area and the real contact area.

Patient Specific Deposition Enhancement of Nasal Sprays in Ct-Derived Human Nasal Replicas. Landon Holbrook, ALYSSA BURKE, Saikat Basu, Elizabeth Monaghan, Julia Kimbell, William Bennett, *University of North Carolina at Chapel Hill*

A patient specific nozzle positioning device (NPD) was developed to enhance delivery of a nasal spray in an individualized nasal model of a patient post functional endoscopic sinus surgery (FESS). Preliminary computational fluid dynamics (CFD) simulations were used to determine administration angles for improved delivery to the maxillary sinus. Penetration depth past the nasal valve was established as a metric to assess improvement compared to standard of care (SOC) use as specified by package insert instructions.

Methods: De-identified sinus CT scans were used to digitally reconstruct the nasal cavity of a patient before and after FESS. Hollow models of the nasal cavity including external nares were 3D-printed in flexible and rigid parts to allow for nostril distension due to the insertion of a nasal spray bottle. The angle of administration was fixed1) according to SOC instructions or 2) for the NPD based on CFD simulation on the post-FESS model results. The NPD was retrofitted for testing on the pre-FESS model without CFD simulations. The SOC use condition was tilting the head at 22.5 degrees forward with an upright bottle inserted to a depth of one centimeter. Steady inspiratory airflow at a flow rate derived from subject weight was drawn through the model during administration of a nasal spray (one spray in left nostril) spiked with the radioactive tracer Tc99m. Radio-aerosol deposition was assessed using a 2D gamma camera. Images of the models in the coronal plane were used to quantify sinus deposition, while images in the sagittal plane were used for penetration measures. Four replicate experiments were conducted to determine the mean and standard deviation (SD) of deposition. Coefficient of variation (CoV) is used to estimate consistency between experiments and is determined by dividing the SD of the deposition by the calculated mean.

Results: Preliminary results for a single subject showed that the mean (SD) fraction of sprayed drug depositing posterior to the nasal valve was 8.0 (2.7) % of the total dose in the pre-FESS model and 11.4 (2.3) % of the total dose in the post-FESS model using SOC administration. Administration of the nasal spray with the NPD produced a mean (SD) fraction of posterior deposition of 12.7 (5.2) % in the pre-FESS model and 15.8 (1.4) % in the post-FESS model. The CoV was 20.4% using the SOC administration and 8.8% using the NPD in the post-FESS model. However, the CoV was 34.2% using the SOC administration and 41.1% using the NPD in the pre-FESS model.

Conclusions: SOC administration of a nasal spray product was measured using gamma scintigraphy and increased 42% when comparing a pre-FESS surgery model to a post-FESS model. Use of the NPD provided a 39.0% increase in deposition posterior to the nasal valve in the post-FESS model. Variability was reduced for the post-FESS model, likely because the NPD was a better fit for this model. Additional subject models are being tested to determine if the NPD will consistently reduce the variability in administered dose. While the novel positioning device coupled with surgery improved delivery of a nasal spray past the nasal valve from 8.0% to 15.8%., there is a remaining 84.2% of the drug depositing prior to the nasal valve that is not expected to provide any therapeutic effect. Supported by NIH HL122154.

4MS.1

MOFs-based Hybrid Nanocomposites for Efficient Gas Capture and Conversion: A Charge Transfer Study. Xiang He, WEI-NING WANG, *Virginia Commonwealth University*

Metal organic frameworks (MOFs) are an exciting class of highly porous polymer crystals with superior surface areas, tunable porosities, and rich functionality, enabling them for a variety of applications in energy and environmental sectors. We have developed aerosol-based synthetic strategies to integrate MOFs with semiconductors to form hybrid nanocomposites for various environmental applications, such as CO_2 adsorption and photoreduction. With increased charge carrier density and efficient CO_2 activation, the hybrid ternary nanocomposite exhibits a high CO_2 conversion efficiency and preferential formation of CH_4. Systematic measurements by using gas chromatography, photoluminescence spectroscopy, X-ray photoelectron spectroscopy, and time-resolved in-situ diffuse reflectance infrared Fourier transform spectroscopy reveal that the semiconductor heterojunction and the coordinatively unsaturated copper sites within the hybrid nanostructure are attributable to the performance enhancements.

Fabrication of Iron Oxide Nanoparticles Deposited on Crumpled Graphene for Supercapacitor Applications.

CHONGMIN LEE, Sun Kyung Kim, Ji-Hyuk Choi, Hankwon Chang, Hee Dong Jang, *Korea University of Science and Technology*

Supercapacitors have attracted considerable attention in recent years because they are able to provide high power density, fast charge process, long cycle life, and low maintenance cost. The performance of supercapacitors is largely determined by the properties of the electrode materials. So far, there are mainly three kinds of electrode materials: carbonaceous materials, transition metal oxides and conducting polymer materials. Among them, transition metal oxides have been widely investigated as pseudocapacitor electrode materials owing to their potentially high specific capacitance. Recently, iron oxides have emerged as alternative electrode materials for supercapacitors because they have advantages of low cost, natural abundance, and environmental friendliness. Graphene loaded with hematite (Fe_2O_3) or magnetite (Fe_3O_4) exhibited enhanced specific capacitance as well as a high energy density. In this study, we present three-dimensional (3D) crumpled graphene (CGR) decorated with Fe_2O_3 and Fe_3O_4 nanoparticles to determine which one can exhibit higher electrochemical performance of supercapacitors. The 3D CGR-Fe_2O_3 and 3D CGR-Fe_3O_4 composites were synthesized in different gas atmospheres from a colloidal mixture of GO and from iron (III) chloride hexahydrate ($FeCl_3 \cdot 6H_2O$), respectively, via one step aerosol spray pyrolysis. Sizes of both iron oxides nanoparticles were ranged from 5 to 10 nm when loaded onto 500 nm CGR. The electrochemical properties of the 3D CGR-Fe_2O_3 and 3D CGR-Fe_3O_4 composites were examined to compare the electrochemical performance of both composite electrodes. The 3D CGR-Fe_3O_4 composite electrode had 16% higher values of capacitance and electrical conductivity than those of the 3D CGR-Fe_2O_3 composite electrode.

Femtoliter Droplet Cloud Evaporation in an Aerosol Reactor. Yuliya Khodyko, SERGEY FISENKO, Wei-Ning Wang, *Luikov Institute of Heat and Mass Transfer*

Results of experimental investigations and simulations of the evaporation of femtoliter water droplet cloud in a laminar flow aerosol reactor are presented. Evaporation of the droplets under atmospheric (continuum regime) and low pressure environments (free molecular regime) are considered. Evaporation of droplets of aqueous solution creates a supersaturated solution inside and it decays via formation of nanoparticles. It was shown that even for temperature wall above 1000 K and reactor length around 1 m, the droplet temperature is significantly decreased by several hundred K. In free molecular regime, the droplet evaporation is running at practically constant temperature. For evaporation in continuum regime, the evaporation rate is strongly depend on droplet radii. Micron-sized droplet practically evaporated during a several hundredths of the second. The larger droplet radius the smaller the solution supersaturation inside it. It is shown that evaporation rate is substantially lower if the number density of droplets increases. The similarity criteria of evaporation and related heat and mass transfer are developed.

Engineered Chitosan and Aerosol Delivery Improve Plant Protection and Reduce Agrochemical Stress on Environment.

Rampura Vishwanath Kumaraswamy, Sarita Kumari, Ram Chandra Choudhary, Shyam Sundar Sahrma, Ajay Pal, RAMESH RALIYA, Pratim Biswas, Vinod Saharan, *Maharana Pratap University of Agriculture and Technology, IN*

Intensive use of agrochemicals for crop protection contributes to environmental pollution, in particular water, food and soil. Moreover, over the period of time, pathogenic microbes develop resistance against such chemical thus effectiveness become lower. Therefore, it is required either to develop the effective antimicrobial agent that can release slowly and in a controlled fashion or resistance in the plants against the pathogenic organism. In the present investigation, we synthesized chitosan (diameter between 200 and 370 nm) decorated with inorganic (i.e Cu) or organic (i.e. salicylic acid) substances. We characterized the engineered chitosan for its stability and physicochemical properties. Further, the chitosan formulation tested on corn and tomato. The formulation was delivered to these plants by a foliar aerosol spray. Resultant we observed that the functionalized chitosan nanoparticles boost the plant resistance by altering reactive oxygen species or mobilizing reserve food. The predictable role of engineered chitosan in plants might be in achieving sustainable plant growth through boosting the intrinsic potential of plants. In-spite of the fact that engineered chitosan abode immense biological activities in plants, these materials have not yet been widely adopted in agriculture due to poor understanding of its bioactivity and modes of action towards pathogenic microbes and in plant protection and growth. Our findings not only highlighted in-depth, various engineered chitosan formulation which has been tested for plant growth and protection mainly against fungi, bacteria and virus but also explained their modes of action.

Detonation Graphene Production Scale Up. JUSTIN WRIGHT, Arjun Nepal, Stefan Bossmann, Christopher Sorensen, *Kansas State University*

We describe our efforts to scale up the production of graphene powders produced by the detonation synthesis method. Historically, the detonation synthesis method began with a tedious gas fill-up phase, and ended with a long clean-out phase. We added electronic flow-meters to speed up the fill-up phase, and tested how fill-up time impacts the quality and yield of the final sample. We also ran tests on the chamber size to prove that the same sample quality and fractional yield was obtained. Finally, to improve the clean-out phase, a system to withdraw the sample after detonation was developed and tested. With all of these parameters, we push to achieve production of 1kg of detonation graphene per day.

4MS.6

The Study of the Role of Morphology and Functional Groups of Crumpled Graphene-based Materials to Determine their Specificity Towards Volatile Organic Compounds in Room-temperature Gas Sensing. KELSEY HADDAD, Siyuan An, Ahmed A. Abokifa, Barani Raman, Fortner John, Pratim Biswas, *Washington University in St. Louis*

Chemiresistive gas sensors, introduced in 1962, detect gases through changes in the electrical resistance of a semiconducting material as a function of the surrounding atmosphere. These gas sensors are already prevalent in areas such as environmental monitoring, domestic safety, and industrial processing for monitoring of toxic gases, including nitrogen dioxide, carbon monoxide, ammonia, and nitric oxide, among others. Graphene-based materials show room temperature gas sensing properties, and the functionalization of graphene is an easy approach to modulating sensitivity; nevertheless, their response suffers from long recovery times. A thorough understanding of the interaction between the sensing material and the analyte of interest is an important step in the practical application of these highly tunable materials for selective gas sensing. Crumpled graphene oxide (CGO), with a minimal tendency towards aggregation while still maintaining the high specific surface area and exceptional electronic properties of flat sheets, offers a potential solution for the integration of reduced graphene oxide into scalable and reproducible chemiresistive sensors.[1-3] Crumpled graphene, in contrast to 2D flat analogs, has not been studied for gas sensing applications. Moreover, the crumpled ridges of the CGO sheets can be considered as line defects, which should enhance adsorption. To date, the majority of studies for graphene and graphene oxide have focused on environmental gases, with no study systematically looking at the role of functional groups or nanostructured materials on sensing volatile organic compounds (VOCs). The diverse responses seen across different classes of VOCs (apolar, monopolar, and bipolar) will be explored to give insight into the interaction mechanisms of graphene oxide and CGO. The role of morphology and functionalization on the sensing response and mechanism of carbon-based materials was systematically explored by crumpling and reducing graphene oxide sheets. Ultimately, the insights gained by correlating the sensor response to analyte and material properties can aid in the construction of an array focused on sensing specific VOC profiles.

Synthesis of Nanoparticle-embedded Composite Films by Plasma-enhanced CVD Process Using Gaseous and Particulate Raw Materials. MANABU SHIMADA, Masaru Kubo, Yuki Shigematsu, Izumo Shimada, *Hiroshima University*

Nanocomposite films consisting of different species are attracting interest, because of the integrated or synergistic properties of the species. Among these, thin films with embedded nanoparticles are promising materials for many applications. The properties of the embedded nanoparticles, such as size and quantity, should sufficiently be controlled in order for desired properties to emerge. One of the beneficial ways to control the properties is to use pre-formed nanoparticles. In this study, nanocomposite films in which silicon dioxide (SiO_2) nanoparticles and carbon nanotubes (CNTs) are embedded in titanium dioxide (TiO_2) matrix are synthesized by a combination of a spray-drying aerosolization technique and plasma-enhanced chemical vapor deposition (PECVD).

TiO_2 matrix is synthesized by feeding titanium tetraisopropoxide (TTIP) vapor in a microwave plasma field. An SiO_2 nanoparticle or CNT suspension is sprayed into the plasma field simultaneously, in which the sprayed droplets are electrically charged and broken-up by Coulomb explosion to generate an aerosol with well-dispersed nanoparticles. This simultaneous feeding of the vapor and nanoparticle aerosol produces the nanocomposite films on silicon and quartz-glass substrates by PECVD. The concentration and size of the nanoparticles in the suspension influenced the morphology and inner structure of the films. Quantitative evaluation of the surface roughness of the films reveals the roughness formation due to the embedded nanoparticles. The photocatalytic activities of the films are found to be enhanced, as compared to that of a TiO_2 film, probably because of the increase in the surface area of the films due to the roughness.

4MS.8

Polymer and Metal Oxides Coating of Multiwalled Carbon Nanotubes by Spray-Assisted Plasma-Enhanced Chemical Vapor Deposition.

LAKSHMIPURA RAMACHANDRAIAH HEMANTH, Keita Nishihara, Masaru Kubo, Manabu Shimada, K. Kusdianto, *Hiroshima University*

Carbon nanotubes have wide applications in every sector due to the tuneable surface property. The low thermal conductivity and surface oxidization of carbon nanotubes limit their applications. To overcome these problems, surface coating is preferred. The coating is performed by physical, chemical as well as by mechanical methods. The present work details about the coatings on surface of carbon nanotubes by polymers and metal oxides by spray-assisted plasma-enhanced chemical vapor deposition (PECVD). Two different streams containing aerosolized multiwalled carbon nanotubes and vaporized methyl methacrylate or metal alkoxides is sprayed simultaneously into plasma; to develop coated carbon nanotubes on a silica substrate by PECVD. The stoichiometry of polymeric materials and metal oxides with focus on retention of desired nanostructures is evaluated. The effects of process conditions such as pre-treatment of nanotubes, carrier gas, flow parameters are analysed. Developed material is characterized basically by X-ray diffractometer, scanning electron microscopy, transmission electron microscopy, FTIR and by Raman spectroscopy. Coated porous polymeric materials on nanotubes surface with thickness of 100-400 nm are obtained under the controlled reaction conditions with acid pre-treatment. Surface morphology of obtained material reveals un-destructed carbon nanotubes with uniform coating of polymer and metal oxides.

4MS.9

Effect of Loading Concentration on the Photocatalytic Activity of Ag-TiO2 Nanocomposite Films Fabricated by One-Step Gas-Phase Deposition. DIANPING JIANG, K. Kusdianto, Masaru Kubo, Manabu Shimada, *Hiroshima University*

It is well known that adding Ag nanoparticles in TiO_2 matrix enhances the photocatalytic performances. It is mainly caused by reducing the electron-hole recombination in photocatalytic reaction due to metal-semiconductor junction. For preparation of Ag-TiO_2 nanocomposites, varieties of routes have been approached which can be categorized as liquid and gas methods, etc. However, fabrication methods included in the liquid methods have disadvantages of having a large number of processing steps, using high temperatures under vacuum conditions, and concern on impurities involved. In this study, Ag-TiO_2 nanocomposite thin films on silicon substrate with different Ag concentrations were synthesized in gas phase by a combination of plasma-enhanced chemical vapor deposition (PECVD) and physical vapor deposition (PVD). The nanocomposite films with different Ag concentrations ranging from 0 to 12.7 wt% were prepared by changing the amount of Ag vapor in the PVD system. It is obviously observed that the crystalline phase, crystallite size, and particle size of the fabricated Ag-TiO_2 nanocomposite films after annealing at 500 °C were affected by the concentration of Ag nanoparticles. The existence of very small Ag nanoparticles (~4 nm) in the films was also confirmed by transmission electron microscopy. Photocatalytic activity evaluated by measuring the degradation of methylene blue aqueous solution under UV light irradiation exhibited that a film with Ag nanoparticle concentration of 5.3 wt% showed the highest photocatalytic performance. This work will be significant not only in the preparation of Ag-TiO_2 nanocomposite films but also in the preparation of metal-semiconductor nanocomposite films which has wide potential applications in photocatalysis, solar energy conversion, antibacterial application, chemical sensors, and so on.

4MS.10

Generation of Iron Oxide Nanoparticles for Follow-up Exposure Studies by MOCVD. PAVEL MORAVEC, Jaroslav Schwarz, Petr Vodička, Jaroslav Kupčík, Jaroslav Švehla, *Institute of Chemical Process Fundamentals of the CAS, v.v.i*

Iron oxide nanoparticles (NPs) are industrially produced and commercially available and they are also frequently emitted into the environment by iron making plants. In the human body, iron is maintained at homeostatic fairly low level. However, freshly generated iron oxide NPs cause febrile and inflammatory response known as metal fume fever, but the potential in vivo consequences of inhalation of iron oxide NPs from the atmosphere has not yet been investigated. In this study we tested a method of long lasting generation of iron oxide NPs by pyrolysis and oxidation of ironIII acetylacetonate (FeAA3).

Experiments were performed in an externally heated work tube with i.d. 25 mm and 1 m long heated zone. A stream of nitrogen carrier gas, saturated by precursor vapours in a saturator (Q_S), was fed into the reactor, where it was mixed either with a stream of nitrogen (pyrolysis) or a mixture of nitrogen and air (oxidation). A stream of NPs laden gas (Q_R) was diluted in the outlet part of the work tube by a diluting stream (Q_{Dil}) of nitrogen (pyrolysis) or air (oxidation). The particle production was studied in dependence on reactor (T_R) and saturator temperature (T_S), and on flowrates Q_S, Q_R and Q_{Dil}, and NPs production was monitored using SMPS (TSI model 3936L75). Samples for NPs characterization were deposited onto TEM grids, using a nanometer aerosol sampler (TSI model 3089) and on cellulose, quartz, and Sterlitech Ag filters. The particle characteristics were studied using HRTEM (*JEOL 3010*), energy dispersive spectroscopy (*INCA/Oxford* connected to *JEOL 3010*), selected area electron diffraction (*JEOL 3010*), inductively coupled plasma – optical emission spectrometry (*Agilent 4200 MP-AES*), elemental and organic carbon analysis (EC/OC, Model 4, Sunset Laboratory) and X-ray diffraction (*Bruker D8 Discover diffractometer*).

Two experimental campaigns in total duration 100 and 80 hours were performed. The NPs production was studied in the range of T_R: 500-800 °C, T_S: 134-141 °C, Q_R: 1400-1500 cm^3/min, Q_S: 120-200 cm^3/min and Q_{Dil}: 1600-1700 cm^3/min. Results have shown that NPs generation by oxidation of FeAA3 at T_R 700 or 800 °C suits for long term inhalation exposure experiments. The generation provides NPs production rate sufficiently high (up to 2400 µg/m^3, i.e. 7.7 µg/min) and can be further increased by an increase of T_S or/and Q_S, and it is stable at steady state conditions for sufficiently long time. Primary particle size is typically between 10-20 nm, the content of Fe varies from 58.7 to 59.6 wt. %, which corresponds to 84.0 – 84.7 wt. % of Fe_2O_3. NPs are free of EC and contain only 3.6 – 5.2 wt. % of OC. Both XRD and SAED method identified cubic Fe_2O_3 crystalline phase, Pdf 32-0469. On the other hand, NPs generation by pyrolysis does not seem to be perspective method for exposure experiments due to poorly defined characteristics of NPs. They contain a lot of EC (32.2 – 37.7 wt. %), the content of Fe varies between 22 and 52 wt. % and because the NPs are amorphous, it is very difficult to identify the form of Fe in NPs.

This work was supported by the Czech Science Foundation under grant P503/12/G147. XRD analyses were performed by Mgr. Petr Mikysek, Geological Institute of the CAS, and EC/OC analyses by Mgr. Věra Procházková, Institute of Chemical Process Fundamentals of the CAS.

Aerosol-assisted Synthesis of Materials for Application in Photovoltaics – TiO2 + Perovskite Layers. ROBIN WHEELUS, Shalinee Kavadiya, Pratim Biswas, *Washington University in St. Louis*

Perovskite solar cells' rapidly increasing power conversion efficiency and cheap cost of production have captured the attention of researchers world-wide and are fundamental reasons why these cells have become one of the fastest growing possibilities for energy production. As mentioned in previous abstracts, however, they face major challenges with stability, particularly in humid conditions. Electro-spray has been developed as a two-step method for perovskite layer formation, allowing for cell fabrication under ambient conditions with both increased efficiency over spin coated cells and relative stability over 5.5 months[1]. The technique is successful largely because of the smooth perovskite surface it produces, which mitigates the perovskite-water interaction. However, electro-spray's effectiveness over a rough surface morphology, like the one obtained from aerosol chemical vapor deposition, has not previously been investigated. This research aims to address questions as to how the electron transport layer (ETL) and perovskite layers interact when the two are deposited using ACVD and electro-spray respectively. Ideally, we aim for a perovskite layer that comes into contact with the entire surface of the electron transport layer in order to take advantage of both the shorter electron pathways from electrons separating at the base of the columns and the increased surface area from the modified morphology. Furthermore, in order to benefit from electrospray's primary advantage, we also want to maintain a smooth perovskite surface above the ETL. We will compare cross-sectional SEM images and power conversion efficiencies for spin-coated and electro-spray deposited perovskite cells with columnar electron transport layers in order to understand and improve the compatibility of these two aerosol techniques in this application.

Attachment Behavior and Aggregation Kinetics of Aerosol Synthesized Oxide Nanomaterials in Water. RAMESH RALIYA, Nathan Reed, Kwon Paul, Tiana Stussie, Patchaya Tobarameekul, Deep Hathi, Patcharin Worathanakul, Samuel Achilefu, Monica Shokeen, Pratim Biswas, *Washington University in St. Louis*

Oxide nanomaterials such as TiO2, Fe2O3, SiO2 and ZnO are manufactured at industrial scale for various applications such as paint, food and cosmetics. Recently, these nanomaterials are being explored for advanced biomedical applications including but not limited to cancer therapeutics, deep-tissue imaging and drug delivery. However, at nanoscale (between 1 and 100 nm at least at one dimension) these particles tend to agglomerate/aggregate very rapidly in the biologically compatible or FDA approved solvents for drug formulation. Because of the aggregation/agglomeration, it is very hard to harness the desired potential of the surface area to volume size phenomenon at the nanoscale[a,b]. In the present study, we investigate mechanistic of oxide nanomaterials aggregation or agglomeration behavior and elucidate the relationship between water chemistry and nanoparticle surface. We compared TiO2, Fe2O3, SiO2 and ZnO nanoparticles synthesized from two different methods, namely- flame/furnace aerosol and sol-gel. Particle stability and aggregation behavior were studied using time-resolved – dynamic light scattering (TR-DLS), and electron microscopy. Surface chemistry of the nanoparticles was characterized by electron microscopy and photon correlation spectroscopy. The data obtained from TR-DLS were used to calculate attachment efficiency of two particles. In summary, the study mechanistically reveals the particles behavior in the solvent and offer solvents conditions (pH, Ionic strength, zeta potential, concentration and physical force) to keep the oxide particles in their monodisperse state independent of the synthesis procedure.

Electrospray Deposition as a Tool for Processing Energetic Polymer Composites. Haiyang Wang, MICHAEL ZACHARIAH, *University of Maryland, College Park*

Electrospray is shown as a tool in the preparation of nanoenergetic based composites with a variety of morphologies ranging from fibers, microparticles composites and thin films, by varying precursor concentrations, binder content, nanoparticle loading and flight time. Examples will be described including the formation of thermite based nanofiber mats with a nitrocellulose composite energetic binder to create a new class of energetic 1-D nanocomposite. Employing electrospray as a means to create a gel within a droplet by evaporation induced rapid aggregation, enables us to generate microparticles of nano-aluminum and oxidizer nanoparticles. We find that the average size of the microparticles can be systematically changed from 2 µm to 16 µm. Finally by preventing drop evaporation the electrospray deposition method is employed to create high loadings of aluminum nanoparticles (Al-NPs) in polyvinylidene fluoride (PVDF) reactive composite films. The deposited films containing up to 50 wt % Al are found to be crack free and mechanically flexible.

In all cases the combustion performance was evaluated by a variety of metrics.

Synthesis of CuO/WO3 and Pt/WO3 Nanocatalysts via Flame-Assisted Spray Pyrolysis and Their Photocatalytic Activity. TOMOYUKI HIRANO, Ogi Takashi, Kikuo Okuyama, *Hiroshima University*

Tungsten oxide (WO_3) has been regarded as visible-light-driven photocatalyst and many other potential applications. However, pure WO_3 shows very low photocatalytic performance under visible light irradiation. One of the promising method to solve this problem, addition of another metal in the WO_3 has attracted attention.

In this work, CuO/WO_3 and Pt/WO_3 nanocatalysts were successfully synthesized using a flame-assisted spray pyrolysis (FASP) method. FASP is an attractive process that enables us to control the particle size, crystal size, and morphology of prepared particles by controlling fuel and carrier gas flow rates, concentrations of precursor, and so on. The flame-made nanocatalysts have strong interconnection between WO_3 and co-catalysts, and they were effective for degrading of aqueous organic pollutant under visible light irradiation. The Pt/WO_3 nanocatalyst exhibited optimal photocatalytic performance with a low Pt concentration of 0.12 wt.%, which is much lower compared to the reported optimal concentrations using a photodeposition technique (0.5–1 wt.%). It is necessary to reduce the required Pt amount in the Pt/WO_3 photocatalysts for large-scale and practical applications.

The addition of CuO enhanced the photocatalytic activity of WO_3 for dye photodegradation under visible light irradiation. The morphology of WO_3 was changed from nanorods to cubic following the addition of CuO. The CuO/WO_3 composite with 0.33 wt.% CuO concentration exhibited the best photocatalytic activity. Furthermore, during a photodegradation test, the as-prepared particles were mechanically stable. Thus, the FASP method is a promising process for the production of a low cost WO_3-based photocatalyst.

Gas-phase Synthesis of Gallium Arsenide Quantum Dots through Hydrogen-assisted Spark Discharge and Its Application.

KIWOONG LEE, Dongjoon Lee, Mansoo Choi, *Seoul National University, Seoul, Korea*

Gallium Arsenide (GaAs) has been considered as one of the most prominent III-V semiconductors because of its extraordinary electronic and photonic properties, such as high electron mobility and direct band gap. Furthermore, because of its large Bohr radius and strong quantum confinement effect, there have been intense effort to synthesize GaAs nanocrystals (NCs) with diameter of under 20 nm. However, despite these advantages of GaAs NCs, there has been inherent difficulties of synthesizing GaAs NCs restricting its applications toward practical devices as well as overall exploration.

Recently, our group introduced hydrogen gas toward spark discharge between silicon (Si) electrodes and demonstrated that hydrogen gas enabled silicon (Si) nanocrystals to be highly pure and crystalline. (D. Lee et al, 2016) In this research, crystallization of Si nanoparticles was based on the scheme in which amorphous Si matrix become crystalline by hydrogen atom's insertion into and relaxation from Si bonds. (S. Srirman, 2002) However, unlike Si, GaAs NCs are hardly obtained by hydrogen-assisted spark discharge since spark discharge energy is not sufficient for the relaxation of hydrogen atoms from GaAs matrix. We identify the amorphous GaAs nanoparticles embedding hydrogen atoms in GaAs matrix via transmission electron microscopy (TEM) and Fourier transform infrared spectroscopy (FTIR). In order to extract these embedded hydrogen atoms and thus to crystallize GaAs nanoparticles, we add heating procedure. After generation of hydrogen-inserted GaAs nanoparticles via hydrogen-assisted spark discharge, these amorphous GaAs aerosols pass through tube furnace with temperature of 950ºC for the desorption of inserted hydrogen atoms. It is demonstrated that fabricated GaAs NCs exhibit high crystallinity through TEM and X-ray diffraction (XRD) measurements.

Additionally, we demonstrate that these GaAs NCs exhibit quantum confinement effects from photoluminescence measurement. We generate GaAs NCs with various size by varying the capacitance of spark discharge circuit from 0.5nF to 6nF, and observe that these GaAs NCs exhibit different photoluminescence peaks according to its size.

Even though there are several other methods of fabricating GaAs quantum dots (QDs) such as chemical synthesis, chemical vapor deposition (CVD), and molecular beam epitaxy (MBE), these methods possess inherent drawbacks, such as expensive installation, undesirable by-products, toxic materials and poor controllability. Since our aerosol-based technique is free from these obstacles, we look forward to our GaAs QDs to be utilized in various applications, such as solar cell, LED, and transistor. In addition, our fabricating GaAs QDs technique is expected to provide an additional degree of freedom in synthesizing various semiconductor quantum dots with high crystallinity.

This work was supported by Global Frontier R&D Program on Center for Multiscale Energy System by National Research Foundation (NRF) under the Ministry of Science, ICT and Future Planning, Korea (Grant no.2012M3A6A7054855).

Production of Cauliflower-like Amphipathic Copolymer Nanoparticles using Aerosol-Photopolymerization. Masoom Shaban, Jalal Poostforooshan, ALFRED P. WEBER, *TU Clausthal*

Amphipathic copolymers consist of hydrophilic and hydrophobic monomer units have attracted great technological attention recently, owing to their unique properties and their ability to stabilize various interfaces in aqueous systems. However, producing these copolymers is still a great challenge in liquid phase due to different polarities of monomers. As a promising alternative to the conventional liquid methods, the polymer nanoparticles can be prepared by an aerosol-polymerization. This method can also avoid the requirement of surfactants and solvents, and produce directly solvent-free dry powders with a high purity and spherical morphology in a continuous process which is desirable in pharmaceutical applications.

The work presented here describes a continuous aerosol-photopolymerization to produce different kind of spherical polymer nanoparticles including polyacrylamide (PAM), polystyrene (PS) and hydrophobically modified polyacrylamide (HM-PAM) *[1]*. The experimental setup is a combination of an atomizer, a homemade flow-through photoreactor, and a collection filter. Initially, the monomer droplets consisting of dissolved photoinitiator were generated by the atomizer. Then, sprayed droplets were passed through the photoreactor, where the free radicals were generated upon UV irradiation within the average aerosol residence time of 30 s in the photoreactor. To control the aqueous solubility, size and morphology of the resulting HM-PAM copolymers, different styrene/acrylamide monomer concentrations were introduced into the system.

The textural properties of the obtained materials were characterized by TEM, SEM, and N2 adsorption-desorption isotherms. The results revealed that the copolymers and polyacrylamide have cauliflower-like morphologies, while polystyrene has a nearly smooth morphology. Moreover, chemical compositions of the obtained materials were investigated by several characterization techniques such as ^{1}H NMR, FT-IR, TGA and elemental analysis. ^{1}H NMR and elemental analysis of resulting copolymers microstructures displayed successful incorporation of styrene in the copolymer with a good agreement compared to initial ratios.

Importantly, the final particle size of resulting polymer nanoparticles could be controlled either by the concentration of solution or flow rate of the carrier gas. As an example, the nanospheres generated with the total initial concentration of 0.195 M and 0.468 M, lead to the average size of 103 nm and 199 nm, respectively.

4MS.18

Preparation of Nanospherical Mesoporous Carbon Nitride with High Surface Area using Aerosol Generated Mesoporous Silica and Its Application as a Photoinitiator for Aerosol-Photopolymerization.

JALAL POOSTFOROOSHAN, Masoom Shaban, Alfred P. Weber, *TU Clausthal*

The work presented here describes a continuous aerosol-based process to produce submicron spherical polymer particles using nanospherical mesoporous carbon nitride (NMCN) as a photoinitiator. In this regard, spherical raspberry-like silica particle was initially synthesized by spray drying of nanocolloidal silica, using polyvinylpyrrolidone (PVP) as a template, within the average aerosol residence time of 6 s in the tube furnace reactor. After removal of the PVP by calcination, spherical mesoporous silica (SMS) nanoparticle was obtained. Then, NMCN with a high surface area and pore volume has been synthesized via a nanocasting approach by using SMS as a hard template through a simple polymerization reaction between ethylenediamine and carbon tetrachloride as precursors *[1]*.

The textural properties and chemical compositions of the obtained materials were investigated by employing diverse characterization techniques such as scanning mobility particle sizer (SMPS), N_2 adsorption-desorption isotherms, transmission electron microscopy (TEM), scanning electron microscopy (SEM), Raman, small-angle X-ray scattering (SAXS), X-ray photoelectron spectra (XPS), FT-IR, wide-angle X-ray diffraction (XRD), thermogravimetric analyzer (TGA), and CHN analyses. The results revealed that the NMCN has a high nitrogen content (16.8 wt%) with a high surface area of ~718 m^2/g, a pore volume of 1.22 cm^3/g and a pore size of 23 nm.

In addition to experimental characterization, the optical properties of NMCN were studied theoretically by three-dimensional finite difference time-domain (FDTD) method. Experimental and simulation results confirm that the introduction of desired mesoporosity in the carbon nitride not only increases the surface area for accommodating active sites, but also improves the light absorption and consequently increases the generation rate of electron-hole pairs inside the NMCN.

Finally, NMCN nanoparticles exhibit excellent performance in photopolymerization of butyl acrylate monomer in the continuous aerosol-based process, within the average aerosol residence time of 90 s in the photoreactor. In this one-pot synthesis, NMCN nanoparticles acting not only as photoinitiators, but at the same time as fillers and templates.

The presented aerosol-photopolymerization process operates at room temperature and avoids the need for solvent and surfactant. More importantly, with this method, we could overcome the problem of producing composites of carbon nitride with hydrophobic polymers. Furthermore, we simulated the condition of NMCN nanoparticles during illumination in the gas phase process which can freely rotate. The results demonstrated that the hole density is almost equally distributed in the whole part of the NMCN nanoparticles, leading to efficient light harvesting and more-homogeneous photoreaction.

4MS.19

Preparation of Core-Shell Nanoparticles by Aerosol-Polymerization Process. JALAL POOSTFOROOSHAN, Masoom Shaban, Alfred P. Weber, *TU Clausthal*

Core-shell nanoparticles, consisting of an inorganic scaffold and polymeric shell, have received considerable attention due to their promising applications. These nanoparticles have the potential to combine different properties of the core and shell into a single particle. Generally, polymer shells on the inorganic nanoparticles prevent particle-particle aggregation and offer excellent compatibility in a polymer matrix.

In this work, inorganic cores were initially generated by either spark discharge followed by the sintering furnace (spherical Ag nanoparticles) or nebulization of the respective suspension (SiO_2 nanoparticles). Then, the inorganic nanoparticle-laden nitrogen flow was bubbled through the saturator containing the glycidyl methacrylate (GMA) as organic monomer kept usually at 80 °C. In the subsequent cooling behind the saturator back to room temperature a supersaturation was achieved resulting in the condensation of GMA vapor on the surface of the inorganic nanoparticle. Subsequently, the monomer coating was chemically polymerized ‘‘in flight’’ to form a polymer shell by addition of ammonia vapor as an initiator within the average aerosol residence time of 2 min in the polymerization reactor *[1]*. Moreover, the effect of numerous parameters, including the GMA saturator temperature and properties of inorganic nanoparticles on the structure of polymeric shell and coating thickness and efficiency has been investigated.

The particle size distribution and morphology of the resulting core-shell nanoparticles have been studied via scanning mobility particle sizer (SMPS) and transmission electron microscope (TEM). Finally, the coating efficiency was determined by aerosol photoemission (APE) and the results showed that monomer and polymer coating efficiency were 99% and 60%, respectively.

Highlights of the presented aerosol-polymerization procedure are the continuous, fast, simple and requires few unit operations. Moreover, in contrast to conventional wet methods such as emulsion polymerization, this technique can produce highly pure surfactant-free polymer shells and allows for a direct collection of composite nanoparticles.

Aerosol Gelation in a Buoyancy-Opposed Flame Reactor: Application to Material Synthesis. PAI LIU, Yang Wang, Jiaxi Fang, Pratim Biswas, Rajan K. Chakrabarty, *Washington University in St Louis*

Aerosol gels are a novel class of materials with potential to serve various energy and environmental applications. Synthesis of aerosol gel materials in gas-phase could be a cost-effective alternative to the conventional wet sol-gel process. Past studies have shown nanoparticle gelation occurring in a down-fired, buoyancy-opposed flame aerosol reactor (BO-FAR) as a viable technique for scalable production of gel materials. However, this gas-phase technique has yet to be proved capable of synthesizing gels with tunable material properties. In this work, we present the results of our experiments specifically aimed at controlling the primary particle properties of gels using a BO-FAR. We were able to optimize the operating temperature conditions of the BO-FAR between 1250 and 590 °C by adjusting the oxidizer dilution ratio. At these two extreme temperature conditions, we delivered Titanium tetraisopropoxide (precursor) to the BO-FAR for producing carbon-free titanium dioxide (TiO_2) gel particles. Our results show approximately tenfold increase in the primary particle size of the TiO_2 aerosol gel with the increase in the flame temperature. Pure rutlile and anatase phase TiO_2 were formed at the high and low temperature conditions, respectively. Our work demonstrates that non-carbonaceous aerosol gel materials can be synthesized through a rapid single-step gas-phase process with high purity and tunable material properties.

Highly Reproducible Large-Area Perovskite Solar Cells Fabricated with Megasonic Spray-Coating. MINCHEOL PARK, Woohyung Cho, Mansoo Choi, *Seoul National University*

The thin-film solar cells using organometal halide perovskite have been establishing rapid rise in efficiency as a highly promising photovoltaic device for solar energy conversion. State-of-the-art devices achieved power conversion efficiencies (PCEs) of 22.1 %; this value surpassing the record efficiencies of amorphous silicon and organic semiconductor PV. As development of perovskite solar cells (PSCs), there have been few reports of scalable film-coating techniques being applied to the deposition of large-sized perovskite films. It is apparent that the path towards commercialization of solution-processed perovskite solar cells requires the development of fabrication methods for linear coating techniques such as roll-to-roll or sheet-fed processing techniques. Large-scalable coating techniques such as aerosol spray, slot-die, inkjet printing, and blade coating show the capability to scalable coat perovskite thin films[1, 2].

Herein, we report a highly promising technique using aerosol coating method generated by megasonic nebulizer also known as megasonic spray coating (MSC). By adapting MSC, efficient and reproducible large-area planar perovskite solar cells (PSCs) were successfully developed. The coating based on mist precursor can be easily operated with low-temperature and antisolvent-free process under ambient conditions. And it can effectively control the volume of $CH_3NH_3PbI_3$ precursor solution and the reaction temperature, which affect the quality of perovskite harvester layers and the performance of perovskite solar cells remarkably. Under optimized condition, the power conversion efficiency (PCE) of devices reach 17.0 % with the average PCE of 16.4 %. The megasonic spray method is also used to fabricate large-area solar cells (1 cm^2) and a PCE of 14.2 % is obtained.

The Formation of Sulfur Trioxide over V2O5/TiO2 Catalyst in SCR of NOx with NH3. YURAN LI, Bin Wang, Jin Xiong, Tingyu Zhu, Shuai Zhang, *Institute of Process Eng., Chinese Academy of Sciences*

The oxidation of sulfur dioxide (SO2) to sulfur trioxide (SO3) is undesirable during the selective catalytic reduction (SCR) of nitrogen oxides (NOx) found in the flue gas of power plants. Sulfur trioxide has a toxicity over ten times than that of SO2 and is highly corrosive, a resource of aerosol. The objectives of this research are to establish the fundamental kinetics and mechanism of SO2 oxidation over supported V2O5/TiO2 catalyst and establish sulfur balance, then, use these insights to propose a basic theory for collaboratively controlling SO3 emissions. A series of supported V2O5/TiO2 catalysts were prepared with various V2O5 contents: 0.5%, 1%, 1.5%, 3%, 4% and 5%. Raman spectroscopy is used to determine the coordination of surface species. Isolated vanadia species were dispersed on the TiO2 surface as Ti-O-V bonds at VOx coverage below the monolayer. Sulfur dioxide temperature-programmed desorption and in situ diffuse reflectance infrared Fourier transform spectroscopy were conducted to study the interaction between SO2 and V2O5/TiO2. It was found that Ti-O-V was demonstrated to play a critical role in the SO2 adsorption and oxidation. A possible reaction mechanism of SO2 oxidation over V2O5/TiO2 catalyst was established in this study. The turnover frequency for SO2 oxidation was very low, approximately 10-5 s-1 at 320℃. Over the range of conditions studied, the rate of SO2 oxidation is zero-order in oxygen and first-order in SO2, and the apparent activation energies for SO2 oxidation was obtained. The decrease of SO2, the gaseous SO3 and the sulfate deposited on catalyst surface were to be quantified by Fourier transform infrared spectrometer (FTIR), PENTOL SO3 analyzer and ion chromatography (IC), respectively. Then, the sulfur balance was established.

Particle Size Distribution and Concentration of Gold Colloidal Nanoparticles. JAESEOK KIM, Min Jeong Kwak, *Korea Research Institute of Standards and Science*

Nanoparticles controlled by size and shape in water are significant to investigate toxicity of nanoparticles. In this present work, we develop well-controlled gold nanoparticles having 30 and 80 nm. The gold nanoparticles were characterized with respect to their shape and size by transmission electron microscopy (TEM) and scanning electron microscope (SEM). Particle size distribution in gold colloidal nanoparticles was determined by the electrospray scanning mobility particle sizer (ES-SMPS) and we compared it with an average particles size measured from dynamic light scattering (DLS). The geometric mean diameter (GMD) obtained by ES-SMPS was in good agreement compared to DLS results.

4MS.24

Constitution Analysis of CNT Aerogel and Its Thermal Property Modification and Characterization. ZHANG XIAO, Adam M Boies, *University of Cambridge*

Due to the outstanding properties of individual carbon nanotube (CNT), their corresponding assemblies, CNT aerogel and corresponding mat have been research hotspots for years as advanced electrical and thermal material. By using the one-step continuous growth technique (floating-catalyst chemical vapor deposition, FCCVD) and continuous collection method, scale up synthesis of CNT aerogel has realized and shown a bright future of CNT aerogel applications.

However, the degradation of properties when individual CNTs were used to form assemblies (including CNT aerogel) have been repeatedly shown in reported and our experiment results.

The large discrepancy between bulk thermal properties and individual CNTs motivated high-fidelity characterizations of CNT constitution after aerogelation, especially individual CNTs' length in aerogel, due to its significant effect on CNT-CNT overlapping length and junctions number in aerogel, and then heat conduction pathway in CNT aerogel.

This presentation will firstly report an ex situ characterization of individual CNTs from the CNT aerogel. De-aerogelation was realized by extracting and isolation of individual CNTs from intertwining CNT aerogel. With dynamic light scattering (DLS) analysis, scanning and transmission electron microscope (SEM and TEM), atomic force microscopy (AFM), UV-Vis-NIR absorption spectroscopy and Photoluminescence and Raman analysis, the constitution unit of CNT aerogel have been characterized systematically with high-fidelity.

For the sake of thermal conductivity improvement on CNT aerogel and mat, with comprehensive understanding on constitution of CNT aerogel, growth parameters during FCCVD have been optimized to get longer individual CNTs before forming a CNT aerogel, which was believed to offer a better heat conduction pathway in CNT aerogel. Moreover, with state-of-the-art steady state thermal conductivity measurement system, we will also show the thermal conductivity modification influence of decorated hexagonal boron nitride nanoflakes on CNTs.

These results will aid in fully realization of perfect individual CNT properties in the CNT aerogel, especially optimization of CNT aerogel thermal properties, so that applications of CNT aerogel can be explored and implemented in sectors such as the automotive and aeronautic industries.

4OF.1

A Review of Radical Chemistry in Oxidation Flow Reactors for Atmospheric Chemistry Research. ZHE PENG, Jose-Luis Jimenez, *University of Colorado-Boulder*

Oxidation flow reactors (OFR) use oxidants at higher-than-ambient concentrations to simulate atmospheric oxidation processes in shorter experimental times than in the atmosphere. The most common OFR type is, by far, uses OH produced by photolysis of H_2O and/or O_3 at using Hg lamp emissions at 185 and/or 254 nm. Because of its portability and promise as an alternative to environmental chambers, as well a recent commercial availability, the use of this type of OFRs in both lab and field is increasing extremely rapidly, and may result in a publication output comparable to that of large chambers in a few years. However, since its oxidant generation is similar to stratosphere, skepticism about the relevance of the chemistry OFRs simulate tropospheric oxidation has persisted in the atmospheric chemistry community. During last few years, a series of studies have been carried out to comprehensively investigate the radical chemistry in OFRs, under what conditions it is tropospherically relevant. We will present a review of recent studies on this topic, with a focus on providing OFR experimentalists with clear guidance about inputs and operating procedures to employ and avoid. First, the radical chemistry of HO_x, NO_y, and organic peroxy radicals (RO_2) in OFRs is discussed in terms of their production and loss. OFR conditions are often similar to those in the troposphere as OH dominates against undesired non-OH effects. The key reason why some conditions lead to tropospherically irrelevant/undesired processing of volatile organic compounds (VOCs) is that under some conditions, OH is drastically reduced while non-tropospheric/undesired VOC reactants are not. Common non-tropospheric/undesired VOC reactants are 185 and 254 nm photons, O atoms ($O(^1D)$ and $O(^3P)$), NO_3 etc. For each of these reactants, we summarize the conditions that enhance their relative importance to OH and the proposed approaches to avoid them, which allow improved OFR experimental design. We also review measures to realize specific experimental goals, the most important one of which is to achieve high-NO conditions. In addition, a number of related experimental issues are discussed, e.g., non-uniformity of UV field, possibility of particle charging by UV, and OH quantification at high precursor and/or aerosol mass loading. In this review, the latest version of estimation equations and OFR Exposure Estimators have been developed and made freely available, and will be briefly described.

4OF.2

Chemical Composition of Secondary Organic Aerosol Generated from Emissions of California Sage Plants Using a FIGAERO-ToF-CIMS. ARCHIT MEHRA, Jordan Krechmer, Andrew Lambe, Chinmoy Sarkar, Leah Williams, Fatemeh Khalaj, James Allan, John Jayne, Hugh Coe, Douglas Worsnop, Celia Faiola, Manjula Canagaratna, *University of Manchester*

Emissions from plants are the main source of atmospheric biogenic volatile organic compounds (BVOCs). Oxidation of BVOCs under ambient conditions results in formation of more oxidised species, many of which have lower volatility than their precursors. These species can partition into the particle phase and contribute to secondary organic aerosol (SOA) formation. To date, the majority of laboratory biogenic SOA experiments have been focused on single or simple multi-component BVOC mixtures that are thought to be representative of Northern Hemispheric deciduous or mixed forest conditions; thus, gaps remain in our understanding of SOA formation from complex mixtures of real plant emissions in other environments. Towards the goal of understanding SOA formation of plant emissions in other source regions, we conducted a series of experiments where Black Sage (*Salvia mellifera*) and California Sagebrush (*Artemisia californica*) plant emissions (the most common plant species in southern California's coastal sage ecosystem) were oxidised in an Aerodyne Potential Aerosol Mass Oxidation Flow Reactor. The chemical composition and the volatility of the SOA were probed with a high-resolution time-of-flight chemical-ionization mass spectrometer equipped with a Filter Inlet for Gases and AEROsols (FIGAERO-ToF-CIMS). Chemical ionization was performed with the iodide reagent ion, which is sensitive to multifunctional oxidized species. Single-BVOC oxidation experiments were also performed with eucalyptol, camphor and camphene, which are the major constituents of the Sage plant emissions. Positive Matrix Factorisation of the FIGAERO-ToF-CIMS mass spectra was used to identify contributions of the individual VOCs to the emission profile of SOA generated from oxidation of the plant emissions. FIGAERO thermograms of SOA generated from standards and the real plant mixture will be presented with the PMF factor results and data interpretation.

4OF.3

Secondary Organic Aerosol Formation and Aging in a Flow Reactor in the Forested Southeast US during SOAS. WEIWEI HU, Brett Palm, Pedro Campuzano-Jost, Douglas Day, Suzane de Sá, Benjamin Ayres, Danielle C. Draper, Juliane L. Fry, Amber Ortega, Lina Hacker, Astrid Kiendler-Scharr, Aki Pajunoja, Annele Virtanen, Jordan Krechmer, Manjula Canagaratna, Samantha Thompson, Laxmi Narasimha Yatavelli, Harald Stark, Douglas Worsnop, Scot T. Martin, William Brune, Steven S. Brown, Jose-Luis Jimenez, *CIRES, University of Colorado, Boulder*

A major field campaign (Southern Oxidant and Aerosol Study, SOAS) was conducted in summer 2013 in a forested area in Centreville Supersite, AL (SEARCH network) in the southeast U.S. To investigate secondary organic aerosol (SOA) formation from biogenic volatile organic compounds (BVOCs), 3 oxidation flow reactors (OFR) were used to expose ambient air to oxidants and their output was analyzed by state-of-the-art gas and aerosol instruments including a High-Resolution Aerosol Mass Spectrometer (HR-AMS), a HR Proton-Transfer Reaction Time-of-Flight Mass Spectrometer (PTR-TOFMS), and two HR-TOF Chemical Ionization Mass Spectrometers (HRToF-CIMS). Ambient air was exposed 24/7 to variable concentrations of each of the 3 main atmospheric oxidants (OH, NO_3 radicals and O_3) to investigate the oxidation of BVOCs (including ambient isoprene-derived epoxydiols, IEPOX) and SOA formation and aging. Effective OH exposures up to 1×10^{13} molec cm^{-3} s were achieved, equivalent to over a month of aging in the atmosphere, although the peak SOA formation was observed for equiv. exposures of about 1 day. Multiple oxidation products from isoprene and monoterpenes including small gas-phase acids were observed in OH OFR. High SOA formation of up to 12 $\mu g\ m^{-3}$ above ambient concentrations of 5 $\mu g\ m^{-3}$ was observed under lower OH exposures, while very high OH exposures led to destruction of ~30% of ambient OA, indicating shifting contributions of functionalization vs. fragmentation, consistent with results from urban and terpene-dominated environments. The highest SOA enhancements were 3-4 times higher than ambient OA. More SOA is typically formed during nighttime when terpenes are higher and photochemistry is absent, and less during daytime when isoprene is higher, although the IEPOX pathway is suppressed in the OFR. SOA is also observed after exposure of ambient air to O_3 or NO_3, although the amounts and oxidation levels were lower than for OH. Formation of organic nitrates in the NO3 oxidation will also be discussed.

4OF.4

Missing Ozone-Induced Potential Aerosol Formation in a Suburban Deciduous Forest near Tokyo. TOMOKI NAKAYAMA, Yuuki Kuruma, Yutaka Matsumi, Yu Morino, Kei Sato, Hiroshi Tsurumaru, Sathiyamurthi Ramasamy, Yosuke Sakamoto, Shungo Kato, Yuzo Miyazaki, Tomoki Mochizuki, Kimitaka Kawamura, Yasuhiro Sadanaga, Yoshihiro Nakashima, Kazuhide Matsuda, Yoshizumi Kajii, *ISEE, Nagoya University*

As a new approach to investigating formation processes of secondary organic aerosol (SOA) in the atmosphere, ozone-induced potential aerosol formation was measured in summer at a suburban forest site surrounded by deciduous trees, near Tokyo, Japan. After passage through a reactor containing high concentrations of ozone, increases in total particle volume (average of 1.4×10^9 nm^3/cm^3, which corresponds to 17% that of pre-existing particles) were observed, especially during daytime. The observed aerosol formations were compared with the results of box model simulations using simultaneously measured concentrations of gaseous and particulate species. According to the model, the relative contributions of isoprene, monoterpene, and aromatic hydrocarbon oxidation to SOA formation in the reactor were 24, 21, and 55%, respectively. However, the model could explain, on average, only about 40% of the observed particle formation, and large discrepancies between the observations and model were found, especially around noon and in the afternoon when the concentrations of isoprene and oxygenated volatile organic compounds were high. The results suggest a significant contribution of missing (unaccounted-for) SOA formation processes from identified and/or unidentified volatile organic compounds, especially those emitted during daytime. Further efforts should be made to explore and parameterize this missing SOA formation to assist in the improvement of atmospheric chemistry and climate models.

Using a Mobile Laboratory Equipped with an Oxidative Flow Reactor to Study Oxidative Aging of In-use Motor Vehicle Emissions. KEREN LIAO, Qi Chen, Yan Zheng, Ying Liu, Tong Zhu, *Peking University*

Vehicle emissions in megacities like Beijing contribute a large amount of gaseous precursors that can form secondary organic aerosol (SOA) via atmospheric oxidation. The contribution of SOA formation from vehicle exhaust to ambient particulate matter concentrations however remains unclear. Most of the current chemical transport models are unable to reproduce the magnitude and the variability of SOA mass in urban regions, suggesting large uncertainties in the emission inventories and/or in the SOA formation mechanism. For the transportation sector, it is important to investigate the SOA formation under actual driving conditions of traffic fleets which has not been studied before in China. We therefore deployed a Potential Aerosol Mass (PAM) flow reactor in a mobile laboratory to investigate the in situ SOA formation from in-use motor vehicle emissions on the major roads in Beijing in 2018. Vehicle exhaust is sampled and delivered into the PAM reactor periodically. The hydroxyl radical exposure in the PAM reactor is cycled from ~ 1 to 10 days of equivalent atmospheric oxidation. Concentrations of traffic-related gaseous precursors and some oxidation products are measured by gas analyzers and a proton transfer reaction mass spectrometer. Chemical composition of fine particles is measured by a time-of-flight aerosol chemical speciation monitor equipped with 2.5-µm lens and a capture vaporizer. The observations are discussed on the basis of the source apportionments of ambient particles from a long-term site. Potential contribution of mobile sources to fine-particle concentrations is estimated.

Evolution of the Complex Refractive Index of Secondary Organic Aerosols during Atmospheric Aging. QUANFU HE, Nir Bluvshtein, Lior Segev, Daphne Meidan, Michel Flores, Steven S. Brown, William Brune, Yinon Rudich, *Weizmann Institute of Science*

Secondary organic aerosols (SOA) from biogenic and anthropogenic sources represent a large fraction of the tropospheric aerosol mass. The optical properties of SOA can vary as a function of wavelength, but only a few studies have reported measurements of the wavelength-dependent aerosol extinction cross section and complex refractive indices, particularly in the visible spectral range. Additionally, there is a large knowledge gap of how the optical properties of SOA in the visible spectral region evolve as a function of atmospheric aging. To address this issue, we applied a novel laboratory instrument to measure aerosol extinction as a function of wavelength from 400 to 650 nm, using a white light-broadband cavity enhanced spectroscopy (BBCES). The instrument was validated by measuring CO_2 Rayleigh scattering cross section and extinction of reference materials. The new system was used to measure the changes in the optical properties of β−pinene and *p*−xylene SOA produced and aged in an oxidation flow reactor (OFR), simulating daytime aging by OH radical exposure under NOx-free conditions. It was found that these SOA are not absorbing in the visible range, and the real part of the refractive index (RI), n, for these two types of SOA showed slight spectral dependence in the visible range. With increased OH exposure, n first increased and then decreased, possibly due to an increase in aerosol density and chemical mean polarizability for SOA produced at low OH exposures, and a decrease in chemical mean polarizability for SOA produced at high OH exposures, respectively. A simple radiative forcing calculation suggests that atmospheric aging can introduce more than 40% uncertainty due to the changes in the RI for aged SOA.

4OF.7

Investigation for the Formation of Secondary Aerosol from Passenger Vehicles by Fuel Types (Gasoline, Liquefied Petroleum Gas, and Diesel). GYUTAE PARK, Sung-Woon Jung, Jounghwa Kim, Seok-Jun Seo, Sunmoon Kim, Kyunghoon Kim, Taekho Chung, Taehyun Park, Heekyoung Hong, Sunhee Moon, Seokwon Kang, Seung Hwan Lee, Min Seok Song, Jihee Ban, Dong-Gil Yu, Youdeog Hong, Taehyoung Lee, *Hankuk University of Foreign Studies*

Recent research proposed that Secondary Aerosol (SA) formation in the atmosphere impacts on air pollution and health effects. However, there has been lack of studies to investigate SA formation all over the world. This study tried to focus on understanding potential mass formation between primary and secondary aerosol by chassis dynamometer for in-use vehicle. The study on potential aerosol formation from different vehicle's fuels was conducted at the facility of Transport Pollution Research Center (TPRC), National Institute of Environmental Research (NIER), Korea. Three different types of fuels such as gasoline, liquefied petroleum gas (LPG) and diesel were tested on the FTP-75 and NEDC driving mode. An oxidation flow reactor (OFR) used in the study was the Aerodyne Potential Aerosol Mass (PAM) flow reactor. The PAM reactor is a cylindrical camber 46 cm long and 22 cm ID with a volume of approximately 13.3 liters. Two UV lamps (185 and 254 nm) are used to produce oxidants (O3, OH, and HO2) in the PAM (referred to as the OFR-185 method), or OH production from photolysis of injected (externally produced) O3 using 254 nm UV lamp (referred to as the OFR-254 method). In this study, OFR-254 method was operated with a residence time in the range of 1-2 min. During the study, relative humidity (RH) and temperature were under 25% and 30℃. Chemical composition of aerosol from vehicle emission and through PAM was measured by the High Resolution-Time of Flight-Aerosol Mass Spectrometer (HR-ToF-AMS). The HR-ToF-AMS provides non-refractory aerosol mass concentrations including nitrate, sulfate, hydrocarbon-like and oxygenated organic aerosol in real time.

Comparison of Composition and Volatility of Soa Formed from Oxidation of α-Pinene and Scots Pine Emissions. ARTTU YLISIRNIÖ, Angela Buchholz, Claudia Mohr, Andrew Lambe, Celia Faiola, Eetu Kari, Taina Yli-Juuti, Sergey Nizkorodov, Douglas Worsnop, Siegfried Schobesberger, Annele Virtanen, *University of Eastern Finland*

Secondary organic aerosol (SOA) formed via oxidation of volatile organic compounds (VOCs) is composed of numerous chemical compounds with different functionalities. These compounds dictate chemical and physical properties of the particles, such as hygroscopicity, viscosity and density. A major part of the chemical complexity of SOA stems from the diversity of the initial VOCs and how these compounds are exposed to different oxidative conditions.

In this study, we investigated how differences in oxidative conditions alter volatility and composition of resulting SOA, when particles were formed from oxidation of either α-pinene or Scots Pine VOC emissions. VOCs were introduced into an Aerodyne PAM oxidation flow reactor (OFR). Volatility and composition of the formed SOA particles were measured utilizing a filter inlet for gases and aerosols on a time-of-flight chemical ionization mass spectrometer (FIGAERO-ToF-CIMS) using iodide ionization. The particles were additionally monitored with an Aerodyne aerosol mass spectrometer (AMS). VOC emissions from Scots Pine seedlings were monitored by proton transfer reaction and gas chromatography mass spectrometry (PTR-ToF-MS, GC-MS).

For α-pinene emissions, we used three different oxidative conditions in increasing trend of oxidative strength termed “low”, “medium” and “high”. Due to varying emission profile from Scots Pines we used fixed oxidative conditions comparable to “medium” case in three separate tree emission experiments and stronger oxidative conditions in one tree emission experiment. The α-pinene results show clear correlation between strength of oxidative conditions and volatility of the resulting SOA: The volatility of the particle phase decreased by ~3 orders of magnitude and approximate O:C increased from 0.65 to 0.9 as the level of oxidative exposure increased. The Scots Pine experiments demonstrate the importance of sesquiterpenes in the oxidation processes as emissions from the trees consisted of 20-50 % sesquiterpenes by mass concentration, which are within the range of values measured from Scots pine emissions in the field. The sesquiterpene-influenced SOA had lower volatility than for any of the α-pinene experiments, even when resulting from oxidative conditions comparable to “medium” exposure.

These results are important for understanding formation and transformation of SOA particles in the atmosphere, since coniferous tree emissions are often assumed to be mostly α-pinene and other monoterpenes.

4OF.9

Volatility Distribution of Primary Organic Aerosol from Food-Cooking Emissions and Its Evolution upon Oxidation.

MANPREET TAKHAR, Arthur W. H. Chan, *University of Toronto*

Food cooking emissions represent one of the most important sources of primary organic aerosol (POA) in urban areas and have been shown to contribute 10-34% of total organic aerosol. However, the evolution of cooking emissions in the atmosphere is not fully understood. The gas-particle partitioning of cooking-related organic compounds is largely determined by their vapor pressures and volatilities, which can also have a significant impact on aerosol chemistry. In this work we study the volatility distribution of primary and secondary organic aerosol (P/SOA) from cooking emissions. We use cooking oils (canola oil, olive oil, peanut oil) as a surrogate to investigate the chemical composition and volatility using thermal desorption-gas chromatography mass spectrometry (TD-GC/MS), and a thermodenuder. In particular, we focus on the composition of intermediate volatile organic compounds (IVOCs) emitted from food-cooking emissions. Heated cooking oil particles were oxidised in a quartz flow tube reactor in presence of ozone or hydroxyl radicals to simulate atmospheric aging. Tenax tube samples and quartz filter samples were collected for analysis of IVOCs and particle-phase organics. We hypothesize that the overall volatility of oxidised cooking aerosol decreases upon oxidation due to addition of functional groups.

The unoxidized cooking emissions were found to be mainly comprised of saturated fatty acids ranging from C12-C20, along with palmitoleic acid, oleic acid, linoleic acid and sterols. The oxidised cooking emissions were comprised of dicarboxylic acids, hydroxy fatty acids, and short chain fatty acids. The organic compounds are therefore becoming more functionalized upon oxidation as hypothesized. The vapour pressures of organic compounds identified in cooking oil samples were estimated based on GC retention times and compared to the temperature dependent volatility distribution measured using the thermodenuder. Upon oxidation, the thermodenuder showed a decrease in the overall volatility as indicated by increased mass fraction remaining at high temperatures. However, the organic compounds identified using GC/MS are smaller and have higher vapor pressures. The inconsistency between the thermodenuder and GC/MS results could be ascribed to a few reasons. The first is the fragmentation of higher molecular weight compounds in the TD-GC/MS due to high desorption temperatures, thus leading to higher apparent volatility. Another possible explanation is the change in the morphology of the particles upon oxidation. Upon oxidation the particles may become sufficiently viscous to hinder evaporation or growth. Thus, while the compounds become more volatile, they also become more difficult to evaporate upon heating. The mass transfer limitations within the particle were investigated using thermodenuder mass transfer models to evaluate the significance. Overall, our results highlight the need to understand both the chemical composition and the particle-phase state to understand the evolution of cooking emissions in the atmosphere.

4OF.10

Assessment of a Field Portable Oxidation Flow Reactor (OFR) Measurement System for Biofuel Emission Characterization in Remote and Rural Settings. ADITYA SINHA, Andrew Grieshop, *North Carolina State University*

Oxidation flow reactor (OFR) experiments in our lab have explored the properties of secondary organic aerosol (SOA) formed from photochemical aging of emissions from cookstoves like those used by billions daily. Lab experiments have explored the physical and chemical properties of SOA formed from emissions for stove types of varying efficiencies, different fuel types (hard and soft wood) and various operating OFR conditions. The OFR simulated up to 18 days of equivalent atmospheric aging and we observed peak organic aerosol (OA) enhancements of about a factor of 3 over primary OA, dependent on stove and fuel types. However, field emission monitoring efforts have consistently shown a clear distinction between in-field performance of cookstoves and that from standardized lab tests. For instance, the primary particulate matter emission factors (PM EFs) measured in the field are often 2 or more times that in the lab[1]. The work presented here builds on previous experiments to develop simplified methods to quantify SOA formation potential from emissions during in-home use of biomass stoves. Typical lab experiments have characterized cookstove emissions utilizing sophisticated instrumentation like the Aerosol Chemical Speciation Monitor (ACSM) and Photoacoustic Extinctiometer (PAX). Since the ability to move and power advanced instruments is limited in remote and rural locations, we are developing an ensemble consisting of portable low power instruments to measure components of interest. We will evaluate this field-portable sensor suite – consisting of optical PM sensors measuring scattering/absorption, CO and CO2 sensors, and filters alongside corresponding lab based instrumentation to assess performance for international rural applications.

Preliminary evaluation indicates that OA enhancement, quantified in the lab using an ACSM correlates fairly well with the enhancement in light scattering coefficient (Bscat), quantified using a PAX. We observe a linear relationship between the OA enhancement and Bscat Enhancement across a range of stove efficiencies, fuel types and aging conditions. This indicates a potential to measure OA enhancement in real time with a portable sensor capable of measuring light scattering. We expect a high degree of inter-test variability in field measurements (for example, organic carbon emissions factors, OC EFs vary by a factor of 2-4[1]) and so it is useful to have a measurement metric that can capture a range of enhancements (up to a factor of 2.8 based on lab testing) across aging equivalent to atmospheric exposure of 1 to 18 days. Filters are a standard method for determining PM, OC and elemental carbon (EC) EFs from a combustion event. In prior lab cookstove emission OFR experiments, we evaluated closure between PM from filters and parallel ACSM measurements. In these comparisons, filters under-predict the OA EFs relative to the ACSM, and so further work is required to evaluate the use of filters for measuring aged OA from an OFR. A hypothesis to be tested is that residual ozone from the OFR, (not fully denuded prior to reaching filters) interacts with and degrades filter-bound organic matter. Experiments will be designed to probe this disparity since filters are often a relatively inexpensive and operationally efficient way to gather important descriptors of OA from a combustion event. Subsequent steps will involve deployment of the OFR along with the measurement suite during the summer of 2018 in Mexico in a rural and remote setting.

Well Mixed, Ambient Conditions and Long Observation Times: Aging Experiments in a CSTR. FRANZ FRIEBEL, Amewu Mensah, *ETH Zürich*

Aerosol particles which are emitted into the atmosphere are exposed to different reactants and therefore change their properties. The average atmospheric lifetime ranges from several hours to more than a week. Experimental approaches which investigate the occurring changes in aerosol particle properties should ideally cover these time scales. Generally, there are two approaches to mimic these time frames. One, the concentration of reactants, e.g. Ozone or OH-radicals can be increased to trigger faster reaction rates e.g. Potential Aerosol Mass (PAM) Oxidation Flow Chambers. Two, larger aerosol tanks can be constructed to extend the observation time e.g. AIDA-Chamber at KIT. Both approaches imply their specific challenges. Treating aerosols with high concentrations of oxidants bears the risk that atmospheric processes are not represented well. An example is the heterogenous oxidation of soot particles with ozone, where the reaction mechanism follows a Langmuir-Hinshelwood kinetic where an elevated ozone concentration does not lead to a faster reaction. Extending the observation time by extending the tank volume is often technically and financially challenging.

Here we present an approach that makes use of the continuously stirred tank reactor (CSTR), a concept well known in chemical engineering but rarely applied in atmospheric science. This approach decouples long observation times from high chamber volumes thereby allowing low reactant concentrations and low aerosol flows.

Generally, aerosol tanks get filled once and provide a flow of aged aerosol until the reservoir is exploited (batch mode). In contrary to that, the CSTR aerosol tank is continuously filled with fresh aerosol and provides a constant sample flow over an unlimited time scale after the tank reached steady state conditions. The sample flow does not consist of a uniform aerosol sample but of a mix of aerosol samples at different aging stages. Nevertheless, statistical challenges in subsequent data analysis can be disentangled by incorporation of the well-defined aerosol age distribution.

From Summer 2016 till winter 2017/18 we conducted several lab campaigns at ETH Zurich where we successfully applied the CSTR aerosol tank concept. Size selected soot particles were exposed to different ozone concentrations (0-200 ppb), at a temperature range of 5°C to 35°C and at different levels of humidity (0-80%) in a 3 m3 stainless steel tank. The setup generated a sample flow of 25 lpm and allowed several instruments to measure the identical and undiluted sample flow for up to 16 h.

An increase of ozone gas phase concentration by a factor of 10 results in a reduction of CCN activation time of only 1.7. At the contrary, a reaction temperature increase of 10 K results in a decrease of activation time by a factor of 1.5 - 2.0. Here, we focus on the underlying principles of CSTR-data analysis and present the advantages of this experimental approach allowing for new insights into atmospheric ageing processes.

Atmospheric Nanoparticle Dry Deposition Velocity. PHILIPPE LAGUIONIE, Luc Solier, Denis Maro, Geoffrey Pellerin, Didier Hébert, Olivier Connan, Oumar-Telly Bah, *IRSN*

In the context of accidental release of radioactive particles into the atmosphere, knowing atmospheric particle dry deposition velocities on ground surfaces is essential to assess risks both on populations and environment. The dry deposition velocity (m s^{-1}): (1) is the ratio of deposition flux (# m^{-2} s^{-1}) over atmospheric concentration (# m^{-3}); (2) has a general applicability as it does not depend on #-entity; (3) depends on the deposition process integrating time-step. The dry deposition velocity depends on the aerosol particle diameter. Currently, there is no in situ dry deposition velocity available in the literature for nanoparticles, whereas it is required to predict deposition of radionuclides as, for examples, ruthenium-106 and iodine-129,131 (reactive gas). In this framework, one of the main challenges is to find a suitable tracer to follow atmospheric nanoparticle deposition at short time scales. In this study, we tested the capability of the naturally-occurring radionuclide bismuth-214 (^{214}Bi, beta emitter, $T_{1/2}$ = 19.7 min) to trace the deposition flux of the atmospheric nanoparticles at hour scale over a grassland (ABBA project, June 2017). ^{214}Bi is a decay product of radon-222 (^{222}Rn, $T_{1/2}$ = 3.8 days) emitted by terrestrial natural radionuclides. ^{214}Bi activity was assumed to be the same as its daughter polonium-214 (alpha emitter, $T_{1/2}$ = 1.6 10^{-4} s) that was quickly counted by a multichamber alpha spectrometer (Canberra, model 7401) located in a mobile lab. Vertical fluxes were calculated using the activity concentration gradient method from samplings on diffusive grids located at 0.7 and 2.7 m above grass. Next, atmospheric activity concentrations were calculated from grid activities using the Jenkings equations. Results showed a significant dry deposition velocity normalized by the shear velocity of 0.06 ± 0.03.

Observational Evidence of Downdraft Clouds Contributing to Daytime Elevated Nitrate Concentration in an Urban Atmosphere. Jun Tao, Zhisheng Zhang, LEIMING ZHANG, Yunfei Wu, Junji Cao, Peng Cheng, Laiguo Chen, Renjian Zhang, *South China Institute of Environmental Sciences*

Nitrate has become the most important hydrophilic chemical component in $PM_{2.5}$ during serious air pollution periods in urban areas of Pearl River Delta (PRD) region of south China, but there is a lack of fully understanding of its formation mechanisms and controlling factors, especially during daytime nitrate episodes. To fill the knowledge gap, water-soluble inorganic ions in $PM_{2.5}$ and trace gases including SO_2, HNO_3, NH_3, NO_x and O_3, particle size distribution, vertical distribution of aerosol backscatter density, and selected meteorological factors were synchronously measured at high time resolution at an urban site in PRD. The remarkably enhanced nitrate mass concentration during daytime were identified to be caused by downdraft cloud processes and related cloud recycling and evaporating of atmospheric aerosols. Cloud downdrafts enhanced more of nitrate and ammonium than sulfate concentrations in ambient air, a finding that may have important implications on the sources of secondary inorganic aerosols in this and other similar cloudy regions.

Aerosols Characterization in Upper Egypt; Urban and Rural Measurements. MOSTAFA MOSTAFA, Hyam Khalaf, Mona Moustafa, Amer Mohamed, *Ural Federal University*

Abstract Mass size distribution of aerosol particles and the elemental composition of Particulate Matter (PM) were examined in rural and urban areas in El-Minia governorate, Upper Egypt. Low pressure Berner cascade impactor was used to collect aerosol particles. Seven elements were investigated including Ca, Ba, Fe, K, Cu, Mn and Pb using atomic absorption technique. Measurements were performed in El-sharyna village representing a rural site and Maghagha city representing an urban site in El-Minia governorate. Meteorological parameters (temperature and relative humidity) were recorded during the sampling. Elemental mass size distributions were founded as a bi-modal log normal distribution corresponding to accumulation and coarse modes. The mass concentrations of the measured elements ranged from 0.58 ng/m3 (for Ba) to 108.7 ng/m3 (for Fe) at El-sharyna village. The mass concentration at Maghagha city ranged from 0.05 ng/m3 (for Ba) to 96.8 ng/m3 (for Fe).

4RA.4

Vertical and Horizontal Distribution of Sub-micron Aerosol Chemical Composition and Physical Properties across Northern India, during the Pre-monsoon and Monsoon Seasons. JAMES BROOKS, Hugh Coe, William Morgan, James Allan, Paul Williams, Dantong Liu, Jim Haywood, Cathryn Fox, Justin Langridge, Ellie Highwood, Suresh Babu, S.K. Satheesh, Andrew Turner, *University of Manchester*

The Indian subcontinent is one of the most polluted regions in the world. At the moment, the nature and magnitude of the aerosol impacts are poorly understood and constrained. Uncertainties lie in the vertical distribution, spatial distribution of various different aerosols and the relative contribution from different sources (Chakraborty et al, 2016).

The South West Asian Aerosol-Monsoon Interactions (SWAAMI) project, which occurred from June to July 2016, sought to address these uncertainties by carrying out an airborne experiment. Such experiment was on-board the UK Facility for Airborne Atmospheric Measurements (FAAM) BAe-146 research aircraft. The field campaign conducted 22 flights in advance of the summer monsoon, and during the onset phase. The vertical and spatial extent of aerosols were studied across both Northern India (based out of Lucknow, in the Indo-Gangetic Plain (IGP)) and in Southern India (based out of Bangalore). Two aerosol instruments were operated by the University of Manchester on-board the aircraft; an Aerodyne Aerosol Mass Spectrometer (AMS) and a DMT Single Particle Soot Photometer (SP2).

In the IGP, organic aerosol (OA) dominates the aerosol burden, whereas outside the IGP, sulphate dominates. BC mass concentrations indicate greater values inside the IGP. The main inorganic components show different spatial patterns; sulphate is regional in nature, especially in the pre-monsoon season. Nitrate appears to be determined by thermodynamic processes, with increased nitrate mass concentration in conditions of lower temperature and higher relative humidity. The total aerosol mass concentrations display decreases as monsoon rainfall arrives over the study regions. However, the decrease is less significant over the IGP, possibly indicative of the strength of emissions sources over this region. Inside the IGP the aerosol species are more absorbing in nature, whereas in NW India aerosol present is larger in size.

The aerosol mass concentration also displays variations in the vertical profiles. Inside the IGP, profiles undergo changes with monsoon progression. During the pre-monsoon, OA and absorbing aerosol species dominate in the lower atmosphere (<1.5km) with sulphate and scattering aerosol species dominating in an elevated aerosol layer (EAL) above (>1.5km). As the monsoon progresses into the IGP region, this EAL structure diminishes, with the profile decreasing in vertical extent, mass concentration and a switch to being dominated by OA. Outside the IGP, the profiles display sulphate aerosol dominating throughout, with no change in chemical composition with monsoon progression (only decrease in vertical extent and mass concentration throughout). Dust is present in the atmospheric column, with large concentrations in NW India and the IGP. The dust concentrations decrease significantly in the IGP due to removal by the monsoon rainfall. These results will serve as useful model input for the SE Asia region.

Predicting Wildfire in United States Using Artificial Neural Network Technique. KAIYU CHEN, Hao Guo, Hongliang Zhang, *Louisiana State University*

Wildfire is the largest source of air pollutants such as particulate matters and toxins, which greatly changes landscape with impacts on human health, large scale climate changes, social economy and ecosystem in the U.S. In this study, Artificial Neural Network (ANN) is applied to simulate the risk of wildfire in the U.S. based on the date recorded from 2000 to 2016. Relationship between wildfire activities, represented by fire occurrence and its brightness and fire radiative power (FRP), with climate factors including temperature (TEM), relative humidity (RH), wind speed (WS) and wind direction (WD) was simulated. Trained by using observation date, our model is reliable to show correlation between climate factors and wildfire activities. Via this model, we are able to estimate fire by detecting climate conditions from closest meteorology station. Results from this study could provide information for wildfire prediction, prevention and controlling management.

Investigation of the Morphology and Chemical Composition of Intra-Urban Atmospheric Particles: Case Study of Tehran, Iran. Balal Oroji, Asghar Sadighzadeh, Eisa Solgi, HOSSEIN YOUSEFI, *Nuclear Science and Technology Research Institute, Iran*

Nowadays, air pollution in cities with regard to its harmful outcomes has been turned into one of the serious challenges in urban management and Tehran city, one of the most polluted cities in the world. As the air pollutant gases concentration is being influenced by environmental factors, the probability of pollution will not be uniform across Tehran. The work described the use of Scanning Electron Microscopy (SEM) combined with X¬-ray Dispersive Energy Spectrometry (EDS) to characterize inorganic atmospheric particles samples collected on PM10 filters from June to October 2017 from five zones within the city of Tehran. Given the wind direction in the region, the particles produced in the urban areas move to the east and north-east during most of the autumn. These particles grow at the time of displacement when dealing with a single-rod and are eliminated with increasing weight when dealing with different levels. Due to the nature of these particles and their subterranean nature, the risk of inhaling particles in the center of the area to the east of the region is more than other areas. The elemental composition of these particles indicates that C, O and Si rich particles were dominant. The other dominated elements were Zn, Ca and Al. This could be inferred as the fly ash origin. These particles can be related to originate from construction activity, regional transport from the urban zones as well as agricultural vegetative burning and natural dust. These particles are composed primarily of feldspar (Ca, Si, Al) and clay (Al, Fe, Si), their origin is mainly crustal, but they can also come from erosion of building products and road dust. Our results indicate that in autumn and winter, the air quality at Tehran is often influenced by regional air pollution as shown by spatial distribution of PM10 concentration. It is found that PM10 had almost the same concentration in regional background air and in different types of urban environments. The special meteorological conditions and the role of regional-scale transport can explain why local abatements in cities cannot lead to significant improvement of the air quality during smog events. These particles morphology and chemical composition, illustrate an abundance of natural elements within the zone. However, some of the elements presented are directly related with human activities, and are of much interest from the public health and environmental perspectives. Due to atmospheric conditions in the region, the suspended particles in the atmosphere are divided into two major groups: urban particles that are the result of combustion of fossil fuels in the region. In the second group, resources are generated outside of the urban boundaries and in the marginal areas of the study area, which mainly consist of particles from dust storms, biomass, as well as moving and fixed resources. Land use change in the western regions of the region and the conversion of vegetation cover and rangelands to residential and industrial areas is the main reason for the production of pollutants in these areas. The shape of these particles is irregular due to the origin of the mineral and due to the presence of biomass particles; they are regular and sometimes spherical forms. Carbon and silica are mainly found in the composition of these particles.

Pollutant Measurements at Near Road and Background Sites. OLIVER RATTIGAN, H. Dirk Felton, Brian P. Frank, *New York State Dept. of Environmental Conservation*

Public concern about the heightened exposure to near-roadway (NR) pollutants had led to a national near-roadway air monitoring program. In New York State monitoring has been ongoing at three urban NR locations. Pollutants measured at these sites include PM2.5 mass, Nitrogen Oxides (NO, NO2, NOx), Ultrafine Particles, Black Carbon (BC) and CO. Measurements at NR sites are usually made in conjunction with existing urban background sites. In general, pollutant concentrations are elevated at the near road site compared to the background site particularly during the daytime hours. At Rochester for example BC at the near roadway site is elevated by a factor of 2.0-3.0 between 7AM and 3 PM dropping to near uniform concentrations at night. The enhancement in BC is highest in summer and lowest in winter. Other co-pollutants including NOx, CO and PM2.5 mass are also elevated at the NR site by varying degrees during daytime hours. The data are used to determine diurnal, weekday/weekend and seasonal patterns. Pollutant source direction is determined through nonparametric wind regression. The data will be used to determine compliance with National Ambient Air Quality Standards.

Source Apportionment and Associated Oxidative Potential of Ambient PM in Beirut during Saharan and Arabian Dust Events. CHRISTOPHER LOVETT, Mohammad Sowlat, Najat A. Saliba, Alan Shihadeh, Constantinos Sioutas, *University of Southern California*

In this study, we examine possible changes in the oxidative potential of airborne particulate matter (PM) in Beirut, Lebanon, as well as the source apportionment of this PM redox activity, that occur during dust events originating in the Sahara and Arabian deserts. Segregated fine (< 2.5 µm) and coarse (2.5-10 µm) PM samples collected during dust events, as well as during non-dust periods, were analyzed for chemical composition and an in vitro alveolar macrophage assay was performed to determine their oxidative potential. To examine changes in the source apportionment of PM oxidative potential during dust events, we first conducted a bivariate correlational analysis of the compositional and biological data to calculate Spearman's rho coefficients. The correlational data indicating associations between PM components and oxidative potential were then used to perform principal components analysis (PCA) of the PM components and then multiple linear regression (MLR) to apportion the measured oxidative potential to distinct source groups and compositional source factor scores. Our findings revealed that the oxidative potential of Beirut's urban PM during non-dust periods was much higher than during dust episodes, and the major contributors to this redox activity were traffic emissions combined with secondary organic aerosols (SOA). During days when aerosols from Saharan and Arabian dust events alter atmospheric PM composition, traffic emissions and SOA continued to dominate as sources of PM oxidative potential, along with the contribution of inorganic secondary ions (SI). The influence of dust aerosols on indigenous Beirut PM did not exacerbate its oxidative potential, thus suggesting that aerosols generated during Saharan and Arabian dust events pose no additional health risks to the population in that area.

Characteristics of Nuclei Mode Atmospheric Aerosol Particles during a Large Scale Fire Event. MANISH JOSHI, Mariam , Pallavi Khandare, Arshad Khan, B.K. Sapra, *Bhabha Atomic Research Centre, Mumbai*

Emission of trace gases and aerosol particles from large scale fires modify atmospheric aerosol characteristics. Such fires include biomass burning, forest fires, volcanic eruptions and accidental fires etc. (Chen et al. 2017; Jaffe and Wigder 2012). Large scale fires have potential to affect aerosol properties and consequently visibility, health and climate. This study focuses on measurements and interpreting modifications in number concentration and number size distribution in the size range 5-350 nm (measured by nano DMA/SMPS) during a large scale fire event (which took place during March 20-27, 2016 at a waste dumping ground in Mumbai, India). Sampling duration was segregated into case and control days and these characteristics were compared for interpreting effect of emissions due to fire on background aerosol characteristics, if any. Temporal evolution of integral number concentration showed several peaks, most of which coincide with simultaneous dip in geometric mean diameter. Data instances when the total number concentration was found to be more than 10^5 per cm^3 were≈ 1.8 % and 0.003% (of all data points) for case and control days, respectively. Similarly≈ 6.5 % and 5.3% times geometric mean decreased lesser than 20 nm for case and control days, respectively. On the days of fire event, formation of nuclei mode particles was noted during noon times. Size distributions for case days were easily differentiated from those of control days even if averaging was done for entire day. Further hourly averaged analysis revealed significant departure from background conditions during noon times only.

Applications of Unmanned Aerial Systems in Atmospheric Environment Monitoring. ZHONG-REN PENG, Xiaobin Li, Dongsheng Wang, Bai Li, *Shanghai Jiao Tong University*

In recent years, unmanned aerial systems (UAS) and miniaturized sensors have been widely used to obtain atmospheric parameters within the lower troposphere. UAS platforms equipped with miniaturized sensors are capable of obtaining both vertical and horizontal distributions of air pollutants, which can be used in many aspects of the environmental science, such as air pollution forecasts and citizen exposure estimation. To explore potential utilization of the UAS platforms as much as possible, we have developed many types of UAS platforms (including fixed-wing and rotor-wing UAS) and used in many field experiments.

The measurement accuracy of UAS platforms under harsh operation environments of upper air was evaluated and calibrated with similar observation of a large tethered balloon platform that was equipped with standard air quality monitors. Results show that the UAS platforms were capable of accurately capturing both horizontal and vertical variations of air pollutants.

The fixed-wing UAS platforms were used to make observations of air pollutants (e.g. O_3 and $PM_{2.5}$) at three-dimensional scales within the 1000 m lower troposphere. Results show that observations of the fixed-wing UAS platforms can clearly demonstrate both vertical and horizontal variations of air pollutants, which can be used to analyze transport characteristics of air pollutants over the experimental area. The rotor-ring UAS platforms were also used to obtain vertical profiles of atmospheric parameters (e.g. O_3, $PM_{2.5}$, temperature, relative humidity, wind speed and wind direction) within the range of 0-1500 m. Observations of the rotor-ring UAS were capable of clearly demonstrating temporal variation patterns of atmospheric parameters, which helped analyze potential causes of air pollution events. Furthermore, the UAS platform was used to calibrate numerical models to obtain more accurate air pollution predictions.

High Temporal Resolution Analysis of Fine Particles Concentrations in 5D Virtual Space. LIBOR HEJKRLÍK, Helena Plachá, Dáša Richterová, *Czech Hydrometeorological Institute*

Number concentrations N of fine particles had been measured by SMPS in 7 channels (10–20 nm, 20–30 nm, 30–50 nm, 50–70 nm, 70–100 nm, 100–200 nm, 200–800 nm) with time resolution of one hour since June 2012 to December 2015 at a background urban site in Northern Bohemia. At the same measuring station of the National Air Pollution Network operated by the Czech Hydrometeorological Institute hourly means of three pollutants had been measured (mass concentrations of SO_2, NO_2 and PM_1 – black carbon). At two nearby climatological stations one-hour values of three meteorological elements were available (air temperature T_h, relative air humidity H_h and global radiation R_h). The whole period of observations covered 1309 days, periodically involving all of the seasons of the year with no respect to weekdays or rush hours. Night hours (R_h=0) were excluded even though they amounted to more than one half of available data. T_h varied between 11,2 °C and 36,1 °C, for H_h it was between 21% and 100% and R_h reached its extremes between 0,2 and 940,5 W/m^2. The maximum of mean concentration of SO_2 slightly exceeded the level 20 µg/m^3/hour, the highest value for NO_2 was registered at 100 µg/m^3/hour and PM_1 was mostly less than 14 µg/m^3/hour. Resulting number of analyzed rows of 5 variables (in two versions, one for SO_2 and another for NO_2) was approximately 14 000. The nearly-continuous combinations of meteorological data were transformed into THREE-DIMENSIONAL matrix where T_h, H_h and R_h were assigned only few discrete values (48, 13 and 13 respectively). In the resulting 8112 cells of the 3D matrix mean concentrations of the modes of fine particles were calculated. To clarify the whole picture only the cells containing at least 15 values of N were taken into account. The results were displayed in the form of XYZ bubble graph, diameters of the spheres being the FOURTH dimension. GrapherTM 11 (Golden Software, LLC) enables colouring of the bubbles regarding specific key, in this case one of four classes of mean hourly concentration of SO_2 or NO_2 in corresponding cells. The colour of the spheres may be regarded as the FIFTH dimension. The nucleation modes of nanoparticles (10–50 nm) demonstrate strong proliferation (N~10^4/cm^3/hour) under extreme both temperature and solar radiation while air moisture remains moderate. The overall picture changes for fine particles with diameter up to 800 nm. Their concentrations are one order less, the maximum values show considerable affinity to periods of low visibility and high humidity. They are possibly primary particles of anthropogenic origin; this is also supported by practically identical graphs for numeric concentrations of particles with diameter 200–800 nm and for mass concentrations of PM_1, obtained by MAAP instrument, it is by different physical method. Highest quantities of nanoparticles correlate with elevated concentrations of sulphur dioxide, whereas concentrations of NO_2 are low. The picture gradually fades out towards 50 nm limit probably due to advancing nucleation of sulphuric acid formed from the atmospheric oxidation of SO_2. Primary particles 50–800 nm reach their maximal values in correspondence with anthropogenically induced high concentrations of sulphur dioxide, probably of industrial origin as well as with elevated values of nitrogen dioxide that is a strong indicator of vehicle emissions.

4RA.12

Measurements and Analysis of Chemical Composition of Urban Aerosol during High Pollution Events at Guanzhong Plain, China.

Junji Cao, LIU HUIKUN, *Key Laboratory of Aerosol Chemistry and Physics, IEECAS*

Aerosol pollution is a serious environmental problem which influencing air quality, regional and global climates, and human health. Aerosol ($PM_{2.5}$) samples were collected at Guanzhong Plain, China with six sampling sites at different cities in the year scale from 2012 to 2014. All of the six sites exhibited highest organic carbon (OC) and elemental carbon (EC) values in winter and lowest values in summer. OC correlates well with EC indicating similar emission sources. The contributions of secondary species SO_4^{2-}, NO_3^- and NH_4^+ in total ions were greatest, and the high concentrations in winter were mainly due to emissions from coal combustion and biomass burning. During autumn the haze days were severest in Xi'an city with similar tendency of $PM_{2.5}$ variations, and it was proved that biomass burning may be the main emission source of the regional pollution. In winter pollution episodes, the pollution patterns in Guanzhong Plain were similar which was resulted from strong secondary reactions and coal burning.Source apportionment using a positive matrix factorization receptor model indicates that on average secondary aerosol was the main source of $PM_{2.5}$ (39.3%), followed by coal burning (17.3%), motor vehicle/industrial emissions (15.7%), fugitive dust (14.9%), and biomass burning (12.8%). The online, in situ measurement airborne species, especially the chemical composition of non-refectory submicron aerosol, during a heavy haze-fog event, was analyzed in detailed.The formation of secondary sulfate and organic aerosol were observed during the event. The sulfur oxidation ratio (SOR), defined as sulfate/(SO_2+sulfate) were mostly over 0.10, with a maximum of ~0.30, when relative humidity > 80%. The aging product of organic aerosol (OA) were also observed in the event. The wet scattering coefficient was influenced by secondary sulfate, in the form of $(NH_4)_2SO_4$, with contribution of 48.9% of wet particulate phase scattering. Thus decreased the visibility dramatically with a minimum of 128m. The current WRF-Chem model study suggested the secondary sulfate formation was essential to the increasing of sulfate concentration. The formation of secondary species was a decisive reason to form severe haze after fog event.

Keywords: $PM_{2.5}$, source appointment, chemical formation

Long Term Satellite Based Study on Aerosol and Trace Gases over the Capital City of Assam, Guwahati. JHUMA BISWAS, Papori Dahutia, *Pandu College, Guwahati, Assam, India*

The variability and trend in aerosol optical depth (AOD) by using the Moderate Resolution Imaging Spectroradiometer (MODIS) level 3 Collection 6 data at 550 nm for the period January, 2004 to December, 2016 and tropospheric columns of nitrogen dioxide (NO2) and sulfur dioxide (SO2) data by using Ozone Monitoring Instrument (OMI) has been studied for the period October, 2004 to December, 2016 over capital city of Assam, Guwahati. The monthly average AOD value varies from its highest value (0.63±0.09) in March to its lowest value (0.23±0.05) in October for the study period over Guwahati. The seasonally averaged AOD reached its maximum in pre-monsoon (0.61 ± 0.06), followed by winter (0.47 ± 0.07) and monsoon (0.41 ± 0.04), with the minimum occurring in post-monsoon (0.25 ± 0.06) season. The observed Ångström exponent value varies from its minimum value (1.18 ± 0.05) in monsoon season to its maximum value (1.35 ± 0.09) in post-monsoon season. Considerable long-term annual increasing trends in AOD, Ångström exponent and tropospheric NO2 column has been observed over the study location. An increasing trend of total number of vehicles along with their emissions degrades the air quality and thereby contributing to the increasing trend of AOD over Guwahati. A significant correlation between long term averaged MODIS AOD and OMI NO2 tropospheric columns with same seasonality indicating their same source of origination. Long term increasing trend in Ångström exponents (~0.008 per year) signify the contribution of smaller size aerosols attributed to urbanization and human activity over Guwahati. The monthly average visibility in Guwahati is highest (27.5 km) in October with a moderate reduction observed during the monsoon, reaching a minimum of 7.2 km in March. With increasing AOD values, horizontal visibility decreases over Guwahati.

4RA.14

Chemical Composition of PM2.5 in Zion, IL during the 2017 Lake Michigan Ozone Study. DAGEN HUGHES, Alissia Milani, Megan Christiansen, Dylan Millet, Timothy Bertram, Charles Stanier, Elizabeth Stone, *University of Iowa*

Areas along the coast of Lake Michigan are consistently in violation of federal air quality standards for ozone. The enhancement of ozone during the springtime and summertime is thought to result from the unique meteorology of coastal regions. In a collaborative effort to better understand ozone production over Lake Michigan, the Lake Michigan Ozone Study (LMOS 2017) took place from May 21 to June 23, 2017, combining airborne, ship, mobile lab, and fixed ground based measurements. Here, we focus on identifying the major sources contributing to fine particulate matter ($PM_{2.5}$) in Zion, Illinois so that the sources contributing to ozone formation can be better understood. Elemental and organic carbon (EC and OC), inorganic ions, organic molecular markers, and metals were quantified in daytime (08:00—20:00) and nighttime (20:30—07:30) ambient $PM_{2.5}$ samples. $PM_{2.5}$ mass concentration ranged from 1.2 – 11.5 $\mu g/m^3$ with an average concentration of 5.3 $\mu g/m^3$. OC levels ranged from <0.5 – 4.7 $\mu g/m^3$ (averaging 4.7 $\mu g/m^3$) while EC ranged from <0.05 – 0.8 μg/m3 (averaging 0.22 $\mu g/m^3$). The average OC:EC ratio was 12.25, suggesting a large contribution from secondary organic aerosol. The most significant contributor to $PM_{2.5}$ mass was organic matter (OM, calculated as 1.7 x OC, contributing 57.9%), followed by sulfate (16.4%), ammonium (6.3%), and nitrate (3.5%). Ozone concentrations exceeded the federal ozone standard of 70 ppb during a high-ozone event on June 02 and during a high-ozone period occurring from June 10 to June 16 where ozone concentrations reached 91 ppb and 88 ppb, respectively. The highest daily average of $PM_{2.5}$ mass occurred during the high-ozone event (10.7 $\mu g/m^3$) and was also elevated during the high-ozone period (6.7 $\mu g/m^3$) as compared to non-event periods (4.6 $\mu g/m^3$). The OC:EC ratio during the June 02 high-ozone event was 7.0—substantially lower than the ratios for the high-ozone period (13.8) and non-event periods (12.0)—suggesting a larger contribution from combustion emissions (higher EC) on this day. The measured species will be used with positive matrix factorization in order to determine sources contributing to fine particulate matter in Zion, IL, with an emphasis on understanding the distribution of primary/secondary and biogenic/anthropogenic sources.

Ice Core Recorded Black Carbon Variations from Muztagh Ata Reveal Kuwait Fires and the Quantitative Evaluation of Source Contribution and Impacts on Glacier Melting. JIAMAO ZHOU, Xuexi Tie, Shuyu Zhao, *Institute of Earth Environment, Chinese Academy of Sciences*

Refractory black carbon (BC) can be transported in the atmosphere from surface to high latitudes and deposited to the ice preserving a history of emissions and atmospheric transport. A yearly resolution BC records from the ice core drilled at Muztagh Ata Mountain are analyzed in order to investigate the BC variations and identify potential source areas by using a global chemical transportation model (MOZART-4). We conclude that the emissions from big Kuwait fires at the beginning of 90s are the dominant source of impurities while the concentrations of BC in the ice core displayed distinct increase by numerical simulation experiments compared with ice core records during the period of Kuwait fires and several pre- and post- years. It suggests that fine BC aerosols from surrounding natural aerosol source regions convectively lifted from the surface boundary layer into the upper troposphere and then integrated with the westerly belt is an effective pathway for BC entering the Muztagh Ata mountains, and increase BC trends in the local glaciers with additional affection by deposition progresses. Quantitative estimation of surrounding sources for the BC concentrations in the Muztagh Ata is firstly carried out by using MOZART-4 model to study the respective transportation pathway and factional contributions. Central Asia is the predominately contribution source region during summer monsoon and South Asia is the largest source during non-monsoon followed emissions from Europe which determined by contemporary emission variation and wet deposition. Furthermore, the albedo reduction and radiative forcing increase caused by black carbon depositing on the surface of snow and ice have been calculated in Muztagh Ata glaciers and BC emissions from the Persian Gult during early 90s had enhanced climate forcing and runoff by over 3 times compared with that of typical normal years. Consequently, emissions in the east part of north hemisphere caused by heavy pollution incidents such as big fires have a tight linkage with BC concentration and deposition trends in the Muztagh Ata. This study provides an important investigation of regional transportation and emissions over east Pamir.

4RA.16

Seasonal Variations of Sahara Dust and Their Impact on the Air Quality over Western Ethiopia- First Cut Results.

SATHEESH M K KUMAR, Amente Dereje Wakgari, *Department of Physics, Wollega University, Nekemte, Ethiopia*

Sahara is the world's largest hot desert lying in low latitude region which spans most of northern Africa (150 to 350 N, 35 0 W to 150 E). Being the second largest arid region after Antarctica in the world and it covers about 9 million square kilometres amounting to 31% land in the African continent, the increasing amount of mineral dust emission from this region plays a pivotal role on the West African air quality and climate (Florence de Longueville et al, 2013). Despite the proximity of the Sahara, virtually no studies related with dust impact on air quality and human health have been initiated in western region of Ethiopia. As Sahara is characterized by periodical outbreaks of dust storms that transport huge amount of mineral dust in the troposphere, it can significantly enhance AOD that is correlated with the aerosol direct radiative forcing (Bart De Paepe et al, 2009, C. Zhao, et al,. 2010). Further, Saharan dust often mix with moist air transported from the Mediterranean build up sporadic clouds which in turn changes the albedo over the western Ethiopian which is lying in a hillock region. This work is a preliminary investigation of air quality variability with the seasonal changes in the direction of air mass over this region with the aid of seasonal changes in the NOAA HYSPLIT back trajectories and the respective changes in the AOD derived from MODIS. This observation further reveals the deterioration of air quality due to the transport of Sahara dust during winter months due to its eastern flow over Ethiopian region. Further, the heavy fog developed in the morning due to the shallow boundary layer across the valley during the winter months contaminated with mineral dust that causes a major health impact in this region with large population. In summer, since the influence of Indian Ocean is more pronounced over this region, the mounting level of moisture induces the development of coarse particles which can vary the weather conditions. The consistent seasonal variations of AOD derived from MODIS over Western African regions ranges from 0.24 to 0.56 reveals the progressive loading of atmospheric aerosols which is in the form different layers also drastically changes the air quality at this region as well (Mamadou Simina Drame et al, 2013). This is the first and preliminary observation from this region and quantification and characterisation of aerosols which are in progress to analyse their prominent role on the variability of air quality in this region.

Chemical Composition and Seasonal Variation of PM2.5 in Urban and Rural Regions of the Guanzhong Basin, Northwestern China.

JIN LI, Gehui Wang, Jianjun Li, *Institute of Earth Environment, CAS*

In order to investigate the character of regional air pollution in the Guanzhong Basin, one of the most polluted areas of China, $PM_{2.5}$ samples were collected at Xi'an in July 2016 and a rural site around 100 km northeast of Xi'an in August 2016 and January 2017, and determined for organic carbon (OC), elemental carbon (EC), and inorganic ions. The concentration of $PM_{2.5}$ in summer was 48.88±22.69 $\mu g \cdot m^{-3}$ and 62.60±14.23 $\mu g \cdot m^{-3}$ in urban and rural areas, respectively, and increased to 161.79±87.05 $\mu g \cdot m^{-3}$ in winter in the rural region. At the rural site, concentrations of OC and EC (41.61±22.03 $\mu g \cdot m^{-3}$ and 12.31±5.51 $\mu g \cdot m^{-3}$) in winter were significantly higher than those in summer (6.75±1.81 $\mu g \cdot m^{-3}$ and 3.80±2.27 $\mu g \cdot m^{-3}$), with no significant differences between daytime and nighttime. The correlation of OC and EC was strong (R^2=0.92) in winter, and much weaker (R^2=0.61) in summer, suggesting an enhanced formation of secondary organic aerosols in summer due to the higher temperature and stronger solar radiation. The water-soluble inorganic ions (WSIIs) accounted for 41% and 48% of $PM_{2.5}$ in urban and rural areas during summer, and 41% in the rural area during winter. Secondary inorganic aerosols (SO_4^{2-}, NO_3^-, and NH_4^+) were dominant WSIIs, accounting for 78-91% of total WSIIs. Contributions of SO_4^{2-}, NH_4^+, and K^+ to $PM_{2.5}$ in the rural area were much higher than those in the urban area, indicating the impact of rural agricultural ammonia emissions and biomass burning. In contrast, the higher contribution of NO_3^- and lower SO_4^{2-}/NO_3^- ratio (8.37±5.31 and 2.14±1.32 in rural and urban areas in summer) suggested a more important emission from vehicle exhaust in the urban area. Our results presented detailed information about chemical composition and source contribution of $PM_{2.5}$ in the Guanzhong region and may be helpful for the government to make effective control and management.

4RA.18

Aerosol Characterization in Oujda (Morocco) for the Period 2011-2015. Ibtissam Marsli, MOHAMMED DIOURI, Abdelouahid Tahiri, Djamaleddine Chaabane, *Atmospheric Physic, LME, University of Oujda, Morocco*

This study focus on the data analysis of aerosol optical characteristics: aerosol optical depth, Angstrom coefficient, refraction index, single scattering albedo, radiative forçage and particle size distribution registered by the network AERONET/PHOTONS. Oujda (34.65 °N, 1.89° W) Northeastern of Morocco, 55Km from the Mediterranean Sea. It enjoys a dry climate with a mild winter to cold and rainy and a hot summer marked by the Mediterranean breeze and the influence of the desert air masses coming from the Sahara, called Chergui wind violent, very dry and hot which blows on North Africa and the South of the Mediterranean Sea. Maritime and continental air masses are the dominant daily changes depending on the general weather.

The seasonal cycle of optical thickness at 0.5µm has two periods: the first extends from October to February with low values and small deviations. The second from March to September with relatively high monthly averages which can reach 0.4 with large deviations. These largest values are associated with small values of the Angstrom coefficients characteristic of the presence of mineral dust in summer coming mainly from Southeast. High values of the Angstrom coefficients result mainly from combustion processes (industrial and domestic), road traffic (arrival of emigrants in summer), and construction sites. These results confirm the importance of desert aerosol in summer and less degree in the spring and are consistent with the measurement campaigns carried out early 2000s. The refractive index varies little with an average real part of the order of 1.475 and of the order of 12.3010-3 for the imaginary part. The monthly spectral averages of the single scattering albedo remain high varying between 0.70 and 0.98; the higher values registered in winter where in the absence of clouds the clarity of the sky is dominant. The radiative forcing observed at the top of the atmosphere varies between -20 and +7W/m2, the negative values corresponding to the increase of the reflected flux due to the diffusion of the radiation towards the larger space by the aerosols thus contributing to cooling of the Earth-Atmosphere system and positive values indicate less reflected radiative energy. At the surface, the observed values vary between -140 and -50W/m2 , and are representative of the importance of forward IR scattering of the coarse particle modes characteristic of desert aerosols which cause a decrease in the net flux.

The seasonal average of PSD for the five years seems identical and show larger amplitudes for the coarse mode around an average radius of 2.56µm and with a maximum recorded in summer for which the volume concentrations can reach 0.24µm3/µm2 and confirms the relative influence of Saharan and desert mineral dust advections. The fine mode present a constant at the general average, and remains less important than that of the coarse with an average radius of the order of 0.15µm.

4RA.20

Aerosol Particle Dry Deposition Velocities above Grassland According to the Diameter and the Micrometeorological Parameters: The "V" Curve between 1.5 nm and 1 µm with Three Different Methods. GEOFFREY PELLERIN, Denis Maro, Evelyne Géhin, Philippe Laguionie, Olivier Connan, Didier Hébert, Luc Solier, *IRSN*

Nuclear facilities introduce different types of radionuclides into the atmosphere in the form of gases and aerosols during chronic or accidental releases. These particles may be submitted to atmospheric dispersion, dry and wet deposition. The study of dry deposition based on the dry deposition velocity (dry deposition flux divided by an atmospheric concentration above the substrates) concept is a major issue concerning the impact of radionuclides on the population and the environment. Uncertainties on the dry deposition velocity values of submicronic particles are up to several orders of magnitude discrepancies according to the model used (Petroff et al., 2008). Moreover there is no data for particle diameter under 10 nm. So, the aim of this study is to quantify dry deposition velocity according the particles diameter and the atmospheric stability.

Dry deposition flux can be determinate with different devices. We used 3 different methods to quantify the dry deposition velocities according the particles diameter. (1): For particles around 1.5 nm we studied the dry deposition of free faction of alpha particles of Rn222 decay products by the gradient method (2) For particles between 2.5 nm and 1.2 µm we used the eddy correlation method with a cospectral analysis (Pellerin et al., 2017): the dry deposition flux is determinate thanks to covariance between fluctuations of the vertical wind velocity and fluctuations of the atmospheric aerosol particle concentration during 30-minutes periods at high frequency. The aerosol particle concentration was measured by coupling two Condensation Particles Counters (CPC 3788, TSI, Inc.) for particle sizes between 2.5 and 14 nm (Twin CPC method) and for particle sizes between 7 nm and 1 µm, an Electrical Low Pressure Impactor (ELPI, Dekati, Inc.) was used. The wind 3-component velocity was measured by an ultrasonic anemometer (Young 81000, Inc.). (3) The last method used is the direct deposition of fluorescein particles of 0.6 µm on synthetic grass and the measurement are carrying on by a fluorimeter.

Four experimental campaigns were conducted above a grassland in western France (near Poitiers) april 2015 and September 2016.

The first results of these campaigns show that the particles under 10 nm are influenced only by the mechanical turbulence (link with the friction velocity u*), while the particles over 10 nm are influenced by the mechanical turbulence and the thermic turbulence (link with the sensible heat flux H).

The different results of dry deposition velocities with the three different methods allowed to obtain a “V” curve between 1.5 nm and 1.2 µm. In fact, if we look the curve of dry deposition velocities normalized by friction velocities according to particles diameter and for the four sampling campaign, even if the used different technics, all of the point are consistent. Moreover we can find the theoretical curve shape of dry deposition velocity with the effects of the three dry deposition mechanisms: Brownian diffusion, interception and impaction.

We propose to present the all used methods and devices and then, to describe the results.

Spatial Distributions and Trends in Aerosol Optical Depth (AOD) from CERES-derived and AERONET-measured over South Asia. NEELESH LODHI, Naresh Kumar Soora, Sachchidanand Singh, *ICAR-IARI, New Delhi Inia*

This study presents variability of aerosol over south Asia and its impact on solar radiation using CERES-derived and AERONET-measured observations for long period (~17 years from March 2000 to June 2016). Spatial distributions and trends are shown for CERES-derived parameters like as aerosol optical depth at 550 nm (AOD550), cloud optical depth (COD), photosynthetically active radiation (PAR) and shortwave (SW) fluxes over India. The CERES-derived monthly mean AOD550 values range from ~0.1 to 1.5 and AERONET -measured AOD500 are from 0.03 to 1.6 over India. The highest monthly mean AOD500 (~1.6) is also found at New Delhi (ground-measured Microtops) and lowest AOD500 (~0.03) at Nainital (AERONET -measured). However, both CERES-derived and AERONET -measured spectral AODs are also high (~1.0) at Delhi, Kanpur and Gandhi College during post-monsoon months possibly due to fossil fuel and biomass burning. The highest increasing AOD550 trends are found at Gandhi College (~0.1/decade) and at IIT Khargpur (~0.12/decade) in lower IGP region due to anthropogenic activities. Moderate increasing AOD550 trends (about ~0.05 to 0.06 per decade) are found at Delhi, Kanpur and Pune due to industrialization and urbanization. Increasing trend of CERES-derived AOD550 is found about 0.03/decade at Nainital, but ground-measured AOD500 values are showing decrease trend. The spatial trend range for AOD550 is from ~-0.12 (54%) to ~0.12 (47%), for COD from~-1.2 (23%) to ~0.7 (26%), for PAR from~-4 (6.1%) to ~5 (6%) and for SW from ~-7 (6.1%) to ~15 (6.5%), respectively over India. The negative trend shows decreasing in both fluxes PAR and SW radiation when increasing AOD550 trend over IGP of India.

Measurement of Particle Concentrations in Southern New Hampshire. ANTHONY BARINELLI, Raymond J. Miller, Luke Parkhurst, Chelsea Bitter, Rudra Aryal, *Franklin Pierce University*

This research focuses on the air quality and air pollutant concentration in the southern area of New Hampshire; Jaffrey and Peterborough. Data was gathered for thirteen straight days using the Purple Air II Monitor, which measures various sizes of particulate matter in the air, including dust particles and traffic emissions, using light scattering techniques. The Purple Air II Monitor data was compared with New Hampshire air pollutant concentrations from the New Hampshire Department of Environmental Services database. The data collected regarding air pollutant levels was averaged into three hour intervals for each day and each day's three hours intervals data was averaged with all thirteen days during the same timeframe. The data found a significant amount of air pollutant concentration during high traffic hours in Jaffrey and Peterborough, compared to low traffic hours. The results demonstrate traffic has a significant effect on the concentration of air pollutants people are exposed to, increasing the risk of illness in those who are exposed to high concentrations of traffic emissions and other air pollutants.

*This research was supported by Franklin Pierce University under faculty funding.

4RA.23

Use of Geostationary Satellite Data for AOD Retrieval over India for Air Quality Assessment. RASMA K., Ratish Menon, Harish Gadhavi, Virendra Sethi, *Centre for Environmental Science and Engineering, IIT Bombay*

Satellite AOD retrieval has been reported to be used for ground level air quality assessment. The acceptability of a specific AOD/satellite product varies from region to region. The launch of TERRA and AQUA polar orbiting satellites with sensors such as MODIS, intended for air quality monitoring, have showed promising results over some parts of the world. Further, AOD products from geostationary satellites have also been found to be useful over US, Europe and Japan. There are limited studies for AOD products for geostationary satellites over India. An AOD product from INSAT 3D Imager was studied by comparison against the data from AERONET. The present study investigates the validation and improvements required for application of INSAT data towards air quality assessment over India.

Key words: AOD, Geostationary, AERONET, air quality

Atmospheric Nanocluster Aerosol Emitted from Road Traffic. HEINO KUULUVAINEN, Topi Rönkkö, Panu Karjalainen, Jorma Keskinen, Risto Hillamo, Jarkko Niemi, Liisa Pirjola, Hilkka Timonen, Sanna Saarikoski, Erkka Saukko, Anssi Järvinen, Henna Silvennoinen, Antti Rostedt, Miska Olin, Jaakko Yli-Ojanperä, Pekka Nousiainen, Anu Kousa, Miikka Dal Maso, *Tampere University of Technology, Tampere, Finland*

Traffic is a significant source of atmospheric aerosol particles. Because of their small size and complicated chemical and physical characteristics, atmospheric particles emitted from traffic pose a significant risk to human health and contribute to anthropogenic forcing of climate. Previous research has established that vehicles emit primary aerosol particles and contribute to secondary aerosol particle formation by emitting aerosol precursors. Our recent studies have extended the characterization of traffic emission to cover the smallest particles of traffic environments, referred as nanocluster aerosol (NCA), i.e. the particles in a size range of 1.3–3.0 nm. In the publication by Rönkkö et al. (2017), we reported the significant presence of traffic-originated NCA particles in the vicinity of traffic, determined the emission factors for the NCA, and evaluated its global importance. Our findings demonstrate that, in urban air, extremely small particles form a significant fraction of the total particle number and are a direct result of road traffic emissions. Thus, our findings also imply that an atmospheric nucleation process is not necessary for the formation of a large number of particles in urban areas.

Concentrations and fractions of NCA were measured in three experiments covering a wide range of urban environments. Stationary measurements were carried out at a roadside environment next to a major road in a semiurban area and in an urban street canyon in Helsinki, Finland. In addition, a mobile laboratory was used for a long-distance on-road study through Western Europe. These measurements were supported by experiments in an engine laboratory where the particle emissions of a modern heavy-duty diesel engine were measured at three different engine load conditions. In the engine laboratory experiments, the exhaust was sampled using a partial flow sampling and dilution system previously proved to mimic the real-world exhaust nanoparticle formation. In all the experiments, the NCA concentrations were measured by using a particle size magnifier (PSM, Airmodus Ltd) together with condensation particle counters (CPC). Also carbon dioxide (CO_2) concentrations were measured parallel with the NCA concentrations in order to determine emission factors for the NCA.

In the semiurban roadside environment, the NCA represented a fraction of 20–54% of the total particle concentration in ambient air. The observed NCA concentrations and fractions were depended on the diurnal pattern of traffic and on the wind direction. The emission factors of NCA for traffic were $2.4\cdot10^{15}$ (kg·fuel)$^{-1}$ in the roadside environment, $2.6\cdot10^{15}$ (kg·fuel)$^{-1}$ in the street canyon, and $2.9\cdot10^{15}$ (kg·fuel)$^{-1}$ in the on-road study. However, the emissions were not associated with all vehicles and all driving conditions. In the engine laboratory experiments, the emission factors of exhaust NCA varied from a relatively low value of $1.6\cdot10^{12}$ (kg·fuel)$^{-1}$ to a high value of $4.3\cdot10^{15}$ (kg·fuel)$^{-1}$ depending on the engine load. The high fractions of NCA observed in urban areas indicate that these small particles may have a significant effect on human health and global climate. The determined emission factors showed that the NCA is directly emitted from road traffic and, by using these emission factors, its contribution can be estimated on a global scale.

Intensive Campaign Measurements in South of Romania. CRISTINA MARIN, Luminita Marmureanu, Simona Andrei, Livio Belegante, Alexandru Dandocsi, *National Institute of R&D for Optoelecttronics, UPB*

The uncertainty in deriving the radiative forcing of the aerosols is originating in insufficient understanding of secondary organic aerosol formation and the aerosol-cloud interaction (IPCC, 2013). The complex atmospheric interactions, the night time and day time chemistry that intervene in aerosol formation represent a challenging task even in nowadays.

The intensive campaigns represent a proper method to extensively characterize the atmospheric physical and chemical processes. The results obtained in AROMAT (Airborne Romanian Measurements of Aerosols and Trace gases) campaign held in Bucharest, in 2016, are presented in this study. AROMAT was supported by ESA in the framework of its Copernicus Earth Observation programme and was a preparatory Cal/Val Campaign. The main objectives were to test newly developed instruments for airborne measurements and to prepare the validation programme of the future atmospheric satellites. The measurements took place in two sites in Romania, visible from the Ozone Monitoring Instrument satellite as important NO2 hotspots (Tg. Jiu Valley where is located the Turceni power plant and Bucharest-the capital of Romania).

In this study are presented the results obtained in the last part of the second AROMAT Campaign, the aerosols and gases evolutions being described for the entire one-week intensive campaign, highlighting the main sources present in the South part of Romania.

In order to study the aerosols and gases variability, the measurement strategy involved simultaneous and collocated active, passive remote sensing and in-situ measurements. A comprehensive "picture" of atmospheric structure and composition on vertical and horizontal was obtained through characterization of the planetary boundary height, the aerosol layers derived from Lidar measurements, submicronic nonrefractory aerosol chemical composition (derived from Aerosol Chemical Speciation Monitor), black carbon concentration (from the Aethalometer) and the gases concentration.

For the entire measuring period, the total average mass concentration of submicronic particles is 6.6 µg/m3, from which organic and sulfate have the highest proportion, 46% and 32%, respectively. The black carbon (BC) originated from fossil fuel represented the mainly part, 86% from the total amount of black carbon. BC resulted from fossil fuel and NOx concentration have similar trend, both indicating the traffic emission as the primary source. The low concentrations of BC resulted from biomass burning are in good agreement with the ACSM marker for levoglucosan, f60. The values for f60 are lower than the threshold value for biomass burning aerosols.

During this time, important sources of local anthropogenic and natural long-range transport are identified. Throughout the campaign an important dust intrusion, confirmed by DREAM model, was detected by also passive and active instruments evidencing the presence of non-spherical particles in the upper layers of the atmosphere and an increased Angstrom exponent.

Aerosol Optical Characteristics of Sub Saharan Area. Rajae Meziane, MOHAMMED DIOURI, *Atmospheric Physic, LME, University of Oujda, Morocco*

The present study is devoted to the aerosol optical characterization including PSD, based on data of Aerosol Optical Depths determined with sun photometric measurements for five Sub-Saharan sites, Bujumbura (3.38S, 29.38E), Mongu(15.26S, 23.13E), Gabon(0.20S,11.60E), Namibia(15.15S, 12.17E) and Pretoria(25.75S, 28.28E) and the Atlantic St-Helena Island (15.94S,5.66W) as a reference site. Measurements are made of AERONET/PHOTONS network set up by the Goddard Space Flight Center (NASA, USA) and the Laboratory of Atmospheric Optics (CNRS, France). Sub-Saharan Africa is composed of several types of climate, the main one being that of the tropical savannah that bypasses the equatorial climate. In the South, the subtropical region at first quite humid then tempered until desert.

The seasonal averages of aerosol optical depth at 0.5µm show two categories with low level less of 0.4 near the southern coast as in Mongo, Durban and Pretoria and high level reaching 1.2 for continental sites as Bujumbura and Gabon. Values for St-Helena do not exceed 0.1 outside disturbances observed on August and September. Seasonal averages of single scattering albedo at all wavelengths varies on a large interval (0.4 to 0.98) for continental sites and on a reduced interval (0.8 to 0.95) for the other sites. The radiative forcing observed at the top of the atmosphere varies between -50 and -120W/m2, expressing the increase of the reflected flux contributing to cooling of the Earth-Atmosphere. At the surface, the observed values vary between -200 and -150W/m2, that quantify the local cooling tendency. This tendency is more accentuated reaching -450 W/m2 in Mongu consistent with the large variability of the observed single scattering albedo, and the high surface albedo.

The monthly means of PSD show very higher amplitudes for both coarse and fine modes respectively around an average radius of 5µm and 0.15µm with a maximum recorded in spring for Gabon and Bujumbura expressing an important natural and anthropogenic local pollution. For the other sites, we observe very lower amplitudes around 0.1 and 4 µm respectively for coarse and fine modes that indicate healthy air consistent with the registered AOD values.

4RA.28

Aerosols Measurements Using an Elastic Lidar in Cubatao, Sao Paulo – Brazil. IZABEL DA S. ANDRADE, Elaine Cristina Araújo, Fernanda de M. Macedo, Renata F. da Costa, Eduardo Landulfo, Thais Correa, Maria Helena G.de A. Salani, Roberto Guardani, Maria Lucia G. Guardani, Marcia T. A. Marques, Daniel S. Lopes, *IPEN*

Cubatao is located in state of Sao Paulo, Brazil. This city was considered one of the most polluted places in the world in the late 1970s, being considerate “the valley of death” by the media. The environmental policies were not very strict, favoring industrialization in the region. Nowadays, the state of Sao Paulo has one of the biggest air quality monitoring network in Brazil and more effective environmental policies, however Cubatao still have some issues with air quality. We performed field campaigns with a scanning three-wavelength elastic LIDAR (Light Detection and Ranging), which is a remote sensing technique, with the objective to identify and measure the aerosols emissions in an industrial area. The obtained results demonstrate the aerosol concentration over the study area, the LIDAR technique also helps to identify places that emitted aerosols to atmosphere.

Single Scattering Albedo in Coastal Cities. Azhare El Khabbouti, MOHAMMED DIOURI, *Atmospheric Physic, LME, University of Oujda, Morocco*

Global demographics continue to grow with a human flow increasingly geared towards coastal cities with a strong interest in heat, visibility and air quality. In this study, we analyse PSD, single scattering albedo and induced radiative forcing. These quantities are determined from measurements of the optical thicknesses of the AERONET / PHOTONS network for a sample of coastal sites of great importance at the human activity level composed of Dakar (14.39N, 16.95W), Hong Kong (22.30N, 114 .17E) and Karachi (24.87N, 67.03E) compared with lower activity ones such as Monterey (36.59N, 121.85W) and Santa Monica (34.01N, 118.47W).

The monthly means of PSD show very higher amplitudes of the order of coarse modes and with less degree for fine modes respectively around an average radius of 2.6µm and 0.16µm with a maximum recorded in summer for Karachi, Dakar and Hong Kong expressing an important anthropogenic and maritime mixture, which constitute the main local pollution. For the other sites, we observe very lower amplitudes about 0.04 around the same median radius that indicate healthy air consistent with the registered AOD values.

The monthly averages of single scattering albedo are between 0.8 and 0.97 with the same trend for visible (440 nm) and infrared (1020 nm) for all sites, and with a value close to 1 for the case of Hong Kong. This implies a very important power of Mie diffusion in coherence with the radiative forcing registered. The seasonal averages of radiative forcing observed at sites with a loaded atmosphere are of the order of -67,09 W/m2 at the surface and -28.82 W/m2 at the top of the atmosphere. While for Monterey and Santa Monica, the values are close to zero at the top of the atmosphere and at the surface, thus reflecting the state of radiative equilibrium characteristic of an aerosol-free atmosphere.

4RA.30

Particulate and Gaseous Emissions from Brake Wear: The Eco-brake Project. FULVIO AMATO, Eleonora Conca, Mery Malandrino, Elio Padoan, Apostolos Salmatonidis, Florence Vivier, Agusti Sin, Jana Kukutschová, *Spanish National Research Council (CSIC)*

Due to the strict regulation of vehicle exhaust emissions in the last two decades, about half of road traffic PM emissions are nowadays composed by non-exhaust particles from brake and tire wear and road dust resuspension. The brake wear emissions are poorly understood due to the large variety of chemical composition of brake pads, emission rates and a standardized method for their measurement. The ECO-BRAKE project aims at estimating emission rates for total PM and its components from conventional and innovative (Cu-free and Sb-free) brake pads, including Semi-metallic, low metallic, non-asbesto organic (NAO) and with different types of binder. Several bench tests were performed in a brake dynamometer simulating the emission rates in the AK Master driving cycle. Particle number and mass size distribution were monitored by means of ELPI+ (Dekati), OPS and Nanoscan (TSI). Size resolved components mass and emission rates were obtained by means of DLPI (Dekati) sampler and subsequent ICP-AES and ICP-MS analysis of particles collected on aluminum foils. Other monitored parameters were absorption CO, and CO2.

Global Survey of Submicron Aerosol Acidity (pH). BENJAMIN A. NAULT, Pedro Campuzano-Jost, Douglas Day, Weiwei Hu, Brett Palm, Jason Schroder, Roya Bahreini, Joost de Gouw, Huisheng Bian, Jack Kodros, Simon Clegg, John Crounse, Jack Dibb, Paul Wennberg, Felipe Lopez-Hilfiker, Eloise Marais, Ann M. Middlebrook, J. Andrew Neuman, John Nowak, Jeffrey R. Pierce, James Roberts, Joel A. Thornton, Patrick Veres, Jose-Luis Jimenez, et al., *University of Colorado-Boulder*

Aerosol acidity (H^+, often expressed as "pH" defined in various ways) is an important property that influences uptake and partitioning of gases, and homogeneous and surface aqueous reactions of key inorganic and organic compounds. As there is currently no rapid method to directly measure ambient aerosol acidity, a thermodynamic model, constrained by both inorganic aerosol species (e.g., NH_4, NO_3, SO_4, Cl) and at least one inorganic gas (HNO_3, NH_3, or HCl), is used to provide reliable estimates of aerosol acidity. In this study, we calculated submicron (smaller than 1 µm) aerosol pH from the NASA ATom, "pole-to-pole" series of aircraft campaigns that cover both the Pacific and Atlantic ocean basins in 4 different seasons. The E-AIM thermodynamic model was used with measurements by an Aerodyne high-resolution time-of-flight aerosol-mass-spectrometer (HR-ToF-AMS) of inorganic aerosol species, along with inorganic gas measurements from other mass spectrometers and ion chromatographs. We compare the results with those for the NASA KORUS-AQ, SEAC4RS, DC3, and ARCTAS aircraft campaigns, as well as several ground-based studies, and NOAA and NSF aircraft-based campaigns. We find urban submicron aerosols are typically highly acidic (pH ~ 1 – 2), although the least acidic compared to other environments. Rural/remote continental submicron aerosols are more acidic (pH ~ 0), and remote oceanic ones are the most acidic (pH ~ -1). We compare these results with results from multiple chemical transport models. We find that the aerosol acidity calculated from the measurements are typically 0.5 – 4 pH units lower than the chemical transport models for all locations around the world. This difference would result in dramatic differences in the calculated rates for some important chemical processes. The differences between the chemical transport models and the results calculated from the field observations are currently being investigated, including the impacts of sea salt emissions, meteorology, and atmospheric burden of ammonia and ammonium on aerosol acidity. These results inform the aerosol acidities that should be used in laboratory experiments of submicron aerosol chemistry. Additionally, we demonstrate the importance of accurate aerosol acidity in chemical transport models to ensure these models are properly representing these uptake, partitioning, and homogeneous and surface aqueous reactions of key inorganic and organic compounds.

5AC.2

Factors Affecting Thermodynamic Modeling of Aerosol pH. MICHAEL BATTAGLIA JR., Rodney J. Weber, Athanasios Nenes, Christopher Hennigan, *University of Maryland, Baltimore County*

Aerosol pH is a fundamental property of aqueous particles that affects many chemical and physical processes in the atmosphere. Presently, aerosol scientists lack the ability to directly measure aerosol pH across all ranges of composition and particle sizes. Because of this, the use of aerosol thermodynamic equilibrium models run with gas + aerosol composition inputs has become the most accurate way to predict aerosol pH. Many aerosol thermodynamic models have been developed, but few systematic comparisons of aerosol pH between models have been carried out. This is especially important for aerosol pH since each model possesses unique constraints and limitations on the composition inputs and solution methodology. In this work, we carry out a detailed analysis of aerosol pH computed with three widely used thermodynamic equilibrium models: the Extended Aerosol Inorganics Model (E-AIM), ISORROPIA-II, and AIOMFAC. We focus on pH differences that arise due to factors previously identified as important: the inclusion of aerosol liquid water associated with inorganic and organic constituents, and treatment of non-volatile cations (Ca^{2+}, Mg^{2+}, K^+, Na^+). We add to this analysis the effects of the hydrogen ion (H^+) activity coefficient calculation, and the activity basis (molality, mol fraction, or molar concentration) used to compute pH. The SOAS campaign is used as the basis for comparison since this dataset has been analysed extensively, including analyses of aerosol pH. Overall, we find the activity basis is the most critical factor when comparing different model results, as pH values computed on different bases can lead to inter-model variations of up to several pH units. The other factors are shown to have a cumulative effect on the model prediction of aerosol pH, but at a lesser magnitude than that of inter-model basis consistency.

5AC.3

Aerosol Acidity in the Southeastern United States and Source Impacts on Fine Particle pH. YU QIAN, Armistead G. Russell, *Georgia Institute of Technology*

Aerosol acidity (pH) plays an important role by affecting aerosol formation, particle composition, human health, nutrient bioavailability, etc. This study used species concentration and meteorological data for three monitoring sites from the Southeastern Aerosol Research and Characterization Study (SEARCH) from 2001 to 2013, and thermodynamic model (ISORROPIA-II) to estimate the daily pH trends over that time period. By using the estimated pH time series data, with the help of multiple methods including both simulation and regression, the control factors of pH and the sensitivities of pH to those factors were investigated. Also based on the source apportionment results for the same domain, multiple-linear-regression models were developed to show the impacts of different source categories on fine particle pH. Aerosol pH in SE US kept low (average 2.61) and did not change much over the past decade with the SO_2 emissions reduction, but significant seasonal patterns were observed: high pH during the winter and low pH during the summer, which mainly caused by higher sulfate concentration during the summer. And spatial variations were also observed: higher pH in the urban area and lower pH in the rural area, which were related to higher NH_3 concentration emitted by mobile and biogenic sources (human activities) in the urban area. Model performance was evaluated by comparing estimated and observed NH_3 gas phase partitioning ratio, which confirmed the model performance by showing a good agreement between those two (averaged slope = 0.87, intercept = 0.1 $\mu g/m^3$, $R^2 = 0.65$). Relative humidity and temperature are proved as two strong driven factors of pH, with high RH tend to raise pH and high temperature tend to decrease pH. pH showed largest sensitivity to two species in this study domain: sulfate (-0.11 unit of pH change per 1 $\mu g/m^3$ change of sulfate concentration) and ammonia (+0.10 unit of pH change per 1 $\mu g/m^3$ change of total ammonia concentration). Crustal ions in SE US have little effect on aerosol pH. With strong correlations (average $R^2 = 0.37$), in most cases, models indicated vehicles emissions had the largest positive impact on pH and ammonia bisulfate contributed most negative impact on pH, even though specific results are different for different seasons and locations. Data withholding methods used for evaluating the model performance indicate that the model is trustable ($R^2 = 0.67$).

5AC.4

RH Effect on the Oxidation of α-pinene and the Influence on New Particle Formation. XIAOXIAO LI, Sabrina Chee, Jingkun Jiang, James Smith, *University of California, Irvine*

It is widely observed around the world that the frequency and intensity of new particle formation (NPF) events are reduced during periods of high relative humidity (RH) due to the combination of diminished solar radiation, which leads to low concentrations of precursors such as H_2SO_4 and low volatility organic compounds, together with increased condensation sink that leads to scavenging of precursors and clusters. However, NPF has also been observed in the free troposphere in vicinity of clouds, where RH is typically usually over 90%. NPF has also been observed when RH is above 80% in winter in Hyytiälä, Finland. Despite these observations, most chamber and modelling experiments related to the formation of new particles and its gas-phase precursors have been conducted in low or medium RH. Overall, laboratory, field and modeling studies disagree as to the potential impacts of RH on NPF. The current study focuses on how high RH affects NPF-related gas phase chemistry and new particle formation. These will be explored under a range of RH from 0-95% using a temperature-controlled flow tube and a continuous-flow reaction chamber. Results from flow tube studies show that high RH will increase the generated particle size, decrease particle number concentration and decrease the concentration of low-volatility gas-phase precursors. To identify and quantify the latter, we developed a new inlet for a chemical ionization mass spectrometer (CIMS) that significantly reduces water clustering on reagent ions, the latter of which confounds the interpretation of mass spectra. A comparison between the new CIMS inlet and a commercial inlet based on the design of Eisele and Tanner resulted in identical spectra when measuring precursors to NPF from α-pinene ozonolysis with an enhancement in sensitivity of more than a factor of 10. At RH above 90%, water clusters dominated the reagent ion spectra when using the commercial inlet, whereas for the new CIMS inlet water clustering is eliminated. Detailed chemical composition of low volatility NPF precursors from α-pinene ozonolysis will be presented in addition to measurements of nanoparticle composition using Thermal Desorption Chemical Ionization Mass Spectrometry.

5AC.5

Competing Effects of Water Vapor and Aerosol Liquid Water on the Yield and Molecular Composition of Secondary Organic Aerosols. LAUREN FLEMING, Julia Montoya-Aguilera, Wing-Sy DeRieux, Ying Li, Peng Lin, Alexander Laskin, Julia Laskin, Manabu Shiraiwa, Sergey Nizkorodov, *University of California, Irvine*

Relative humidity (RH) is known to affect the mechanism of gas-phase oxidation of volatile organic compounds (VOCs) that ultimately affects the formation and growth of secondary organic aerosol (SOA). Additionally, high RH results in aerosol liquid water (ALW) associated with an inorganic component, which is known to promote the formation of SOA by oxidizing water-soluble components in the aqueous-phase. These two effects of RH can in many cases counteract each other. For example, it has been shown that the toluene SOA yield decreases with increasing RH in experiments without hygroscopic seed particles and increases with increasing RH in those that use them. The goal of this study was to decouple the gas-phase RH effect and ALW chemistry by investigating the effect of RH and presence of aerosol liquid water (ALW) on the relative yields and chemical composition of various SOA types. In addition, we carried out experiments aimed at understanding the ALW effects on SOA organic compounds over time scales of days, comparable to aging times for SOA particles in the atmosphere. Deliquesced (liquid) or effloresced (solid) ammonium sulfate seeds were prepared in a smog chamber at 90% RH and <5% RH, respectively. The photooxidation of α-pinene or xylene occurred in the presence of conditioned ammonium sulfate seeds at the set RH. In a control set of experiments, no seed was used. A suite of online instruments monitored gas-phase composition (proton transfer reaction time-of-flight mass spectrometer), particle-phase composition (aerosol time-of-flight mass spectrometer), and particle volume concentration (Scanning Mobility Particle Sizer). Filter samples were collected for offline ESI-HRMS and/or DART-MS analysis, which provided molecular composition of SOA. SOA filter samples were aged at 85% RH or 0% RH for 24 hours and their molecular composition was subsequently probed. A "molecular corridor" analysis of the nano-DESI mass spectra resulted in the volatility distributions for SOA produced in the presence and absence of ALW for both SOA samples. Additionally, the SOA's glass transition temperature was estimated in order to predict particle phase state under different atmospheric conditions. The results of this study underscore the importance of the effect of gaseous and liquid water on the chemical composition and key properties of SOA particles.

5AC.6

Insights into Aqueous-Phase Related Secondary Organic Aerosols via Mass Spectrometers in Winter in Urban Beijing.

JIAN ZHAO, Conghui Xie, Weiqi Xu, Wei Du, Qingqing Wang, Wei Zhou, Pingqing Fu, Douglas Worsnop, Zifa Wang, Yele Sun, *Institute of Atmospheric Physics, CAS*

Haze pollution, characterized by high levels of fine particles (PM2.5, i.e. particulate matters with aerodynamic diameter less than 2.5 micrometers), had become a major concerning in megacities in China. Here, we deployed an HR-ToF-AMS with other collaborated on-line aerosol instruments including a SMPS, a CAPS extinction and an AE33 from 17 December to 30 December 2016 during the Air Pollution and Human Health (APHH)-Beijing winter campaign in an urban site. Overall, submicron aerosol species varied drastically with an average value of 126.65 (+96.22) µg m-3, which is much higher than the historic PM1 mass concentrations obtained in recent years, while the contribution of each species to NR-PM1 did not show large differences since 2010, indicating relatively stable sources of NR-PM1 during winter time in urban Beijing among these years. In addition, six OA components including three POA factors (CCOA, BBOA and COA) and three SOA factors (LO-OOA, aq-OOA and MO-OOA) were identified by PMF analysis. On average, CCOA contributed the most among POA to OA with 18.4% and LO-OOA dominated SOA with 31.3% (of OA). The aqueous phase related OOA (i.e. aq-OOA) was clearly identified during high RH period and correlated well with aerosol liquid water content and sulfate mass concentrations. Furthermore, aq-OOA together with a fog related factor (F-OA) and interstitial OA observed in Fresno, California fell into the same square region in triangle plot (f44 vs. f43), which might could define a specific region for aq-OOA in this plot. Finally, filter samples were off-line analyzed by FIGAERO-I-CIMS for aqueous phase related tracers to investigate its properties and the potential processes.

5AC.7

Oxidation of Polycyclic Aromatic Hydrocarbons in Secondary Organic Aerosol Particles. AMBER KRAMER, Kaitlyn J. Suski, Alla Zelenyuk, Staci L. Simonich, David Bell, *Oregon State University*

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental pollutants which are transported globally on fine particulate matter (PM2.5). Secondary organic aerosols (SOA) are formed through atmospheric reactions of natural biogenic volatile organic compounds, making up a large fraction of PM2.5. Global SOA particle mass has been shown to be increasing due to anthropogenic activity, and have been shown to trap and transport PAHs. SOA particles consist of highly oxidized organic compounds as well as reactive oxygen species. These reactive oxygen species have the potential to react with other organic components such as PAHs. In controlled laboratory experiments, ozone reacted α-pinene SOA was produced with four individual gas phase PAHs present: phenanthrene, dibenzothiophene, pyrene, and benz(a)anthracene. Particles were monitored for changes in physical characteristics, exposed to ozone, and observed over time. Filters of SOA particles were collected and analyzed using gas chromatography mass spectrometry for PAHs and PAH oxidation products. Oxidation products of the experimental PAHs were observed to be in equal concentrations with the parent compound put into the system. The PAH chemistry was observed to change when particles were exposed to 6-10 ppm ozone, using a potential aerosol mass (PAM) oxidation chamber, as well as when particles were analyzed after sitting undisturbed in the reaction chamber for two hours. Data indicates SOA particles are dynamic with continuing chemical reactions occurring.

5AC.8

Fine Particle pH for Beijing Winter Haze as Inferred from Different Thermodynamic Equilibrium Models. SHAOJIE SONG, Meng Gao, Weiqi Xu, Jingyuan Shao, Guoliang Shi, Shuxiao Wang, Yuxuan Wang, Yele Sun, Michael McElroy, *Harvard University*

pH is an important property of aerosol particles but is difficult to measure directly. Several studies have estimated the pH values for fine particles in North China winter haze using thermodynamic models (i.e., E-AIM and ISORROPIA) and ambient measurements. The reported pH values differ widely, ranging from close to 0 (highly acidic) to as high as 7 (neutral). In order to understand the reason for this discrepancy, we calculated pH values using these models with different assumptions with regard to model inputs and particle phase states. We find that the large discrepancy is due primarily to differences in the model assumptions adopted in previous studies. Calculations using only aerosol phase composition as inputs (i.e., reverse mode) are sensitive to the measurement errors of ionic species and inferred pH values exhibit a bimodal distribution with peaks between −2 and 2 and between 7 and 10. Calculations using total (gas plus aerosol phase) measurements as inputs (i.e., forward mode) are affected much less by the measurement errors, and results are thus superior to those obtained from the reverse mode calculations. Forward mode calculations in this and previous studies collectively indicate a moderately acidic condition (pH from about 4 to about 5) for fine particles in North China winter haze, indicating further that ammonia plays an important role in determining this property. The differences in pH predicted by the forward mode E-AIM and ISORROPIA calculations may be attributed mainly to differences in estimates of activity coefficients for hydrogen ions. The phase state assumed, which can be either stable (solid plus liquid) or metastable (only liquid), does not significantly impact pH predictions of ISORROPIA.

5AM.1

Linked Response of Aerosol Acidity and Ammonia to SO2 and NOx Emissions Reductions in the US. ABIOLA LAWAL, Xinbei Guan, Cong Liu, Lucas Henneman, Vasudha Bhogineni, Rodney J. Weber, Athanasios Nenes, Armistead G. Russell, *Georgia Institute of Technology*

Reductions in sulfur (SO_2) and nitrogen oxides (NO_x) emissions have led to considerable improvements in air quality such as lower particulate matter ($PM_{2.5}$) concentrations. However, similar responses in aerosol acidity have not been observed. Aerosol acidity is an important characteristic of particulate matter ($PM_{2.5}$) that has far wide-reaching implications in atmospheric heterogeneous chemistry, biogeochemical cycles, climate forcing and adverse health effects. Studying the impact of the reduction of SO_2 and NO_x emissions, both of which can ultimately constitute a large portion of inorganic aerosol mass fraction, is important to understanding the environmental impacts of future emissions reductions on acidity. Previous spatially limited studies have shown that effects of these precursor emission reductions have had minimal impact on aerosol acidity[1]. Other studies involving a thermodynamic analysis into the neutralizing effectiveness of ammonia (NH_3(g)) on aerosols have shown limited impact of high ammonium concentrations on aerosol acidity[2]. This study expounds upon previous aerosol acidity analysis by conducting a longer temporal and wider spatial study over the continental United States using data from three nationwide ambient concentration networks; the Ammonia Monitoring Network (AMoN), the Clean Air Status and Trends network (CASTNET) and the Southeastern Aerosol Research and Characterization Network (SEARCH) together with a chemical transport model (CMAQ). Further, as aerosol pH is not readily measured, the aerosol thermodynamic model, ISORROPIA II is utilized here to characterize aerosol pH. Results of the study show that aerosol acidity has not responded to nationwide reductions in SO_2 and NO_x, with all observed increases yielding changes in pH of less than 1 unit over varying periods of time. Additional results also show no significant changes in particulate nitrate or atmospheric gaseous ammonia concentrations in response to these reductions. In effect, our study finds nationally, what has been reported for the southeast US[1]; the significant emission reductions in SO_2, NO_x did not significantly impact aerosol acidity. What are the implications of these findings? Maybe a more important question is when, if ever, will the aerosol system become more sensitive or respond differently to these emission reductions.

Improving SOA Formation in the Source-oriented WRF/Chem Model (SOWC) in Southeast US and the Air Quality and Climate Impacts. HONGLIANG ZHANG, Anikender Kumar, Michael Kleeman, *Louisiana State University*

Aerosols from natural and anthropogenic sources could affect climate by directly absorbing and scattering radiation and indirectly acting as cloud condensation nuclei (CCN). Key features affecting aerosols’ radiative forcing ability such as the primary source origins, differential secondary formation coatings, and mixing state are not well represented in current air quality and climate models. The source-oriented WRF/Chem model (SOWC) tracks particles from different sources separately and has the ability to better predict the aerosol-meteorology-climate interactions. This study, new secondary organic aerosol (SOA) formation pathways (the aging process, aerosol surface uptake and effect of vapor wall loss) are incorporated in the SOWC to investigate the climate effects in Southeast US. Summer 2013 is selected to take advantage of the extensive measurements from field campaigns. The Sparse Matrix Operator Kernel Emissions (SMOKE) Modeling System is used to generate source-oriented anthropogenic emissions from the National Emissions Inventory (NEI) 2011. The increase of SOA predictions from each improvement will be quantified and the feedbacks of aerosols to meteorology and climate will be estimated. The results of this project would also encourage the scientific community to include these features in global climate models for long term simulations to reevaluate the past and predict the future.

Improved Prediction of Aerosol Optical and Chemical properties over the Indian Subcontinent from Constrained Aerosol Simulation.

Bharath Kumar, SHUBHA VERMA, Olivier Boucher, Rong Wang, *Indian Institute of Technology Kharagpur*

Role of aerosols in influencing the hydrological cycle is evidenced through studies with aerosol-chemistry-climate models. These studies are required specifically for the Indian subcontinent, as monsoon precipitation being a crucial element of economic growth in India. However, a large divergence between simulated and observed aerosol distribution over the Indian region limits the accuracy in prediction ability of aerosol-climate interactions over the region. This divergence is typically large over the Indo-Gangetic plain, where the atmosphere is observed laden with a high pollutant level of aerosol load. Due to the inclusion of various complex physical-chemical atmospheric and aerosol processes in aerosol-chemistry-climate models, in conjunction with inherent uncertainty in inputs to the model, e.g. aerosol emissions and their properties, a systematic approach is, therefore, required to improve the prediction of aerosols.

With the aim of obtaining a better concurrence between model estimates and observations of atmospheric aerosol chemical constituents and predicting their spatial distribution as consistently as possible, we performed a free running aerosol simulation (freesimu) in a general circulation model (GCM), and further constrained the simulated with the observed aerosol optical depth (AOD). Constrained aerosol simulations are used to establish an alternate approach for estimating the atmospheric concentration by surpassing the error induced specifically due to emissions in source regions which prevails in case of the free running aerosol simulations. The present study was carried out during the pre-monsoon season and for the Tigerz experiment which was conducted at stations over the Indo-Gangetic plain (IGP) and the Himalayan foot-hills in northern India. Our formulation of the constrained aerosol simulation (constrsimu) was based upon an identification of the freesimu with the most consistent estimates of aerosol characteristic among the three freesimu (differing in the source of emissions and resolution) carried out in the GCM of Laboratoire de Météorologie Dynamique (LMD-ZT GCM).

Estimates from constrsimu revealed a good concurrence with the observed counterparts. Black carbon (BC), organic carbon (OC), and sulfate-other water soluble (Sul-ows) constituents estimated from constrsimu amounted to 70%–100% compared to that from freesimu being 20%–50% of their measured counterparts. Also, a good agreement between constrsimu estimated aerosol constituents and the respective observations confirmed the postulation of our formulation that the lack of anthropogenic emissions in aerosol simulation in GCM-indemiss being the primary reason for a large discrepancy between model and observations over the mainland India. Estimates from constrsimu were further used to examine the pattern of the distribution of pre-monsoon mean of aerosol species optical depth and concentration over the Indian subcontinent. Among the aerosol constituents, the pre-monsoon mean of dust concentration from constrsimu was considerably high over most of the Indian subcontinent, the anthropogenic aerosol constituents were, however, specifically predominant over the IGP. While the high value of observed AOD was found being mainly due to dust (>0.3) over the northern–northwestern IGP, it was due to Sul-ows (as high as 0.4) over the eastern IGP, eastern coastline, and the Bay of Bengal.

Improved prediction of aerosol constituents as obtained from constrsimu over the Indian subcontinent region gives an insight on prognostic improvement in free running aerosol simulations in the GCM. This information is also useful towards a more realistic estimation of aerosol-induced radiative perturbations and their climatic implications over the region.

5AM.4

Important Role of Ammonia in New Particle Formation in the Earth's Atmosphere. FANGQUN YU, Alexey Nadykto, Gan Luo, Jason Herb, James Schwab, Joseph P. Marto, Junying Sun, Xiaojing Shen, Kirill Nazarenko, Lyudmila Uvarova, *University at Albany*

New particle formation (NPF, or nucleation) is an important source of atmospheric particles and cloud condensation nuclei (CCN), impacting air quality, hydrological cycle, and climate. Ammonia is the most abundant base molecule in the atmosphere, and has been observed to enhance nucleation in a number of laboratory studies. Despite intensive research over the past two decades, questions remain about the role of ammonia in NPF, including the detailed nature of the physico-chemical processes underlying the observed impacts of NH3 on aerosol nucleation rates and properties. Here we employ the thermodynamic data derived from both quantum calculations and experimental measurements to quantify the physio-chemical processes of NH3 nucleation enhancement, and present a comprehensive kinetically-based H2SO4-H2O-NH3 ternary ion-mediated nucleation (TIMN) that explicitly resolves the dependence of nucleation rates on all major controlling parameters. We show that the presence of NH3 lowers the nucleation barriers for neutral, positively charged, and negatively charged clusters differently, as a result of large difference in the binding strength of NH3, H2O, and H2SO4 to small clusters of different charge states. The model reveals the general preference of nucleation on negative ions, the necessity of relatively high [NH3] to initiate nucleation on positive ions, and even higher [NH3] required to achieve neutral nucleation. The predicted dependence of TIMN rates on [NH3], [H2SO4], ionization rates, temperature, and relative humidity agrees well with laboratory measurements. The newly developed TIMN scheme has been implemented into regional and global models (WRF-Chem, GEOS-Chem, and CESM-CAM5), and evaluated against NPF measurements taken at a site in the heavily polluted area around Beijing, China, and another site in the relatively less polluted northeastern region of the US. We show that TIMN schemes reproduce well the observed NPF events and non-events, and ammonia plays an important role in promoting NPF in the lower troposphere. The implications of the results will be discussed.

Aqueous Formation of Low Volatile Organic Compounds using Coupled CMAQ-MCM-CAPRAM. QI YING, Jingyi Li, Jianlin Hu, *Texas A&M University*

Many of the secondary organic aerosol modules in current air quality models assume equilibrium partitioning of semi-volatile organic compounds with an absorbing organic phase. However, water soluble organics have been identified to account for a significant fraction of ambient organic aerosol mass, suggesting that the aqueous phase on aerosols and fog/cloud droplets may have significant contributions to secondary organic aerosol (SOA). In a previous study, the semi-explicit Master Chemical Mechanism (MCM) was incorporated into the Community Multiscale Air Quality (CMAQ) model (i.e. the CMAQ-MCM-SOA model) to study regional SOA formation by gas-to-organic phase partitioning of thousands of semi-volatile organic compounds (VOCs). In this study, a detailed chemical aqueous phase radical mechanism based on CAPRAM 3.0i was coupled with the CMAQ-MCM to predict the regional formation of low volatile oxygenated VOCs (OVOCs) in aerosol and cloud water. The CAPRAM mechanism treats detailed oxidation pathways of 34 oxygenated organic species of two to six carbons (including 5 alcohols, 10 carbonyl compounds, 13 mono- and dicarboxylic acids, 1 ester, 4 polyfunctional compounds and 1 heterocyclic compound) with ~400 model species and ~ 830 reactions. 3D regional simulations will be carried out for the TexAQS 2006 to evaluate the importance of these low volatile OVOCs in SOA predictions in southeast Texas.

Parametrisation of the Multi-Component System: HOM+H2SO4+NH3, Measured by the CERN CLOUD Experiment.

Simone Schuchmann, HAMISH GORDON, Ken Carslaw, Jasper Kirkby, CLOUD Collaboration, *CERN*

Low-volatility vapours in the atmosphere lead to new particle formation (NPF). The change in particle concentrations over the industrial period that results from changing rates of NPF can lead to a radiative forcing of the climate [1]. The most important gases involved in NPF are probably sulphuric acid, ammonia, and highly oxidised organic molecules (HOMs) [2].

Radiative forcing via changes in cloud albedo can be estimated using a global aerosol model. These models are based on parametrisations of ambient and laboratory measurements, and tested against observations of particles in the atmosphere [3]. NPF leads to over half of particle number concentrations at the level of low clouds [4] and is therefore an important variable to constrain.

The CLOUD collaboration has published studies of the nucleation rate $J_{1.7nm}$ for the pure biogenic system with HOMs [5] and for H2SO4+NH3 [2]. Within these reports, parametrisations were presented, that are implemented in the GLOMAP aerosol model. However, ambient data show that there are locations where HOMs, H2SO4 as well as NH3 are present in significant quantities [6]. In addition, recent (unpublished) CLOUD measurements suggest that the interaction of sulphuric acid, ammonia and HOMs leads to different NPF rates compared to a sum of the individual contributions of these molecules to NPF. To study $J_{1.7nm}$ for the multi-component system (HOMs, H2SO4 and NH3), CLOUD has also measured this system for different temperatures, ionisation states and relative humidities between 2015 and 2017. In this contribution, we will present a parametrisation of this multi-component system and compare the results of GLOMAP including this new mechanism to older model versions.

We thank CERN for supporting CLOUD with important technical and financial resources and the PS beam. This research has received additional funding from numerous sources.

Application of Boosted Regression Trees Technique to Analyse Particle Number Count Concentrations [PNC] at the East Coast of Malaysia. NOOR ZAITUN YAHAYA, Siew Moi Phang, Azizan Abu Samah, Intan Nabila Azman, *Senior Lecturer, Universiti Malaysia Terengganu, Malaysia*

Study on Particle Number Count Concentrations ([PNC]) were conducted at The Institute of Ocean and Earth Sciences (IOES), University Malaya in Bachok, Kelantan, Malaysia, which located approximately 100m from sea edge of the South China Sea at the east coast of the Peninsular Malaysia.

The study focused to understand particle patterns, temporal and relationship between the meteorological factors (wind speed, direction, humidity, temperature and pressure) and gasses that influence the [PNC] in coastal environment. A one-minute data from 6th January to 5th July 2015 (n=259,200) were collected from the IOES station. [PNC] data were obtained by using Particle Counter GRIMM Model EDM180 which built in with 31 channels and located estimated 20 meter above the ground level. [PNC] data were grouped into two, which are fine particles (FPNC) and coarse particles (CPNC), with diameter between 0.265-2.25µm and 2.75-9.25µm respectively. Statistical data analysis was carried out by using a comprehensive statistical software R programming language and its packages.

FPNC were found are more dominant particle in this area,compared to the CPNC with the maximum of FPNC 5,204,079 counts/liter and only 907 counts/liter recorded by CPNC. A resembling pattern was showed throughout the period, which the increasing number of fine particles starting from early May to mid of June, due to the South-West Monsoon effects. Compared to the FPNC, there were decreasing numbers of particle during the North-East Monsoon (January to March). This shows that particles concentrations is influenced mostly by the speed of the wind and from where it blew from (wind direction).

The Boosted Regression Trees (BRT) model was constructed from multiple regression models, and the best iteration of BRT model was performed by optimizing prediction performance. The FPNC and CPNC model were developed with nine variables in three categories namely time system (time in a day, Julian day), meteorological factors (humidity, temperature, pressure, wind speed, wind direction) and gases (SO2, NOx). The BRT algorithm with combination of parameters lr=0.001, tc=5 and nt=10,000 for both [PNC] that achieves minimum predictive error were found best fit the data. The FPNC and CPNC R(R2) values were found to be 0.87 (R2 = 0.75) and 0.85 (R2 = 0.72) respectively, which indicates both observed and model [PNC] were good correlation to each other. The FAC2 values for both [PNC] are 0.81 and 0.76, which are in the recommended range, which is in between 0.5 to 2. The COE values for both [PNC] are 0.56 and 0.54 respectively, which show the models were in a predictive advantage as the value were approaching to 1. In this case, the developed model was within the acceptable value range for predictive evaluation performance. The analysis demonstrates significant variations in FPNC, largely influenced by SO2 (64.12%), prevailing wind direction (11.82%) with the physical strength index, H-Index = 0.097. Meanwhile the other variables show less than 10% influenced with the FPNC. Contradict to FPNC, CPNC largely influenced by wind speed, Julian day and wind direction, which are 29.84%, 22.46% and 22.17% respectively, followed by other parameters which are 10% and less. The H-Index values for CPNC, wind speed and wind direction is 0.219.

BRT model has the ability to identify the most influential variables and rank it in percentage which very useful for planner, designer and policy maker to take into their considerations in their work. The used of a boosting regression trees model in has proven as a statistical tool for predicting of particles at the coastal environment specifically and for other different area in general.

Understanding Significant Variations of Particle Formation and Number Concentration from Surface to the Upper Troposphere over the Central Pacific Ocean. GAN LUO, Fangqun Yu, Charles Brock, Agnieszka Kupc, Christina Williamson, *The State University of New York at Albany*

Aerosol impacts significantly on cloud properties by serving as cloud condensation nuclei (CCN). The sources of CCN over remote oceans and key controlling parameters remain to be understood. Significant variations of particle formation and number concentration from 0.2 to 12 km altitude over the Central Pacific Ocean area were observed during the ATom first deployment (ATom-1, Aug 3rd-9th, 2016). To better understand the key factors controlling particle formation and number concentration from surface to the upper troposphere, a state-of-the-art global chemistry model with sectional advanced particle microphysics package (GEOS-Chem/APM) is employed in this study to simulate particle formation and size distribution evolution. The predicted condensation nuclei larger than 3 nm (CN3) and other variables along ATom-1 NASA DC-8 tracks are compared with those observed. Major characteristics of CN3 vertical distribution and variation sampled along NASA DC-8 tracks have been captured quite well by GEOS-Chem/APM. CN3 concentrations in the upper troposphere are generally ~10-100 times higher those near the surface and have the highest values over the tropical regions. Our study indicates that particle number concentration is dominated by new particle formation, and key parameters controlling nucleation rates include gas concentrations of sulfur acid and ammonia, temperature, ionization rate, and relative humidity. Precursor gases are transported from surface to the upper troposphere via convection, which result in high sulfur acid gas concentration, nucleation rate, and particle number concentration in the upper troposphere over tropical pacific oceans. The key parameters controlling the growth of new particles and their contribution to CCN at different altitudes over the remote oceans will be discussed.

5AP.1

Understanding the Partitioning of Water and Secondary Organic Matter Using Optically Trapped Single Particles.

STEPHEN INGRAM, Young-Chul Song, David Topping, Simon O'Meara, Jonathan P. Reid, *University of Bristol*

The physicochemical changes experienced by organic aerosol particles undergoing dehydration into the surrounding gas phase can be drastic, with persuasive evidence supporting the existence of a moisture driven glass transition in secondary organic aerosol (SOA) particles.[1]

However, at present, the influence of aerosol in a glassy and ultraviscous state on the partitioning of semi-volatile organic compounds (SVOCs) between the particle and gaseous phases is not clear. Indeed, it may not be governed by equilibrium thermodynamics at all, but instead kinetic factors.

We will begin by presenting recent developments[2] in assessing the evaporation kinetics of water and an SVOC from benchmark ternary aerosol, where both chemical species volatilise in response to a step change in relative humidity (RH).

We find that the contributions to observed size behaviour from each process can be decoupled and treated separately.

Particles are levitated in a standard optical tweezer instrument[3] and sized continuously by analysis of characteristic stimulated peaks in the Raman spectrum. Employing Fickian diffusion modelling4, we extract the compositional dependence of the diffusion constant of water and compare the results to recently published parametrisations in binary aerosol particles.

With reference to a numerical framework developed by Mai et. al.[5], we claim that particle phase diffusivity is also crucial to the timescale and reversibility of SVOC evaporation. Such kinetically limited mass transport manifests as a suppression in the observed vapour pressure above the droplet surface, and could have ramifications for mass loadings and size distributions of organic aerosol, were it to be a common phenomenon under atmospheric conditions.[6]

Moving up in complexity, we also present more recent experiments involving the gas phase ozonolysis of α-pinene in the atmosphere surrounding (dry) saccharide or inorganic particles. Oxidation products of varying volatility are produced which condense onto the surface of the seed particle. The volatility these compounds are then estimated from the size response of the organic shell once the gas phase chemistry is stopped.

It is observed that, under dry conditions, particle phase diffusion of organics is completely arrested: only the outermost layers of SVOC partition back into the gas phase, consistent with a recently proposed non-equilibrium adsorption model of particle growth[7]. Conversely, under humid conditions, equilibrium is approached and a distribution of organics are observed to volatilise without impedance.

By cycling the RH within the optical trap in this way, it is also possible to homogenise and re-vitrify the resultant droplet, encasing the organic mass in a nonvolatile, glassy matrix at a range of water activities. This allows the effect of different particle morphologies (core-shell vs homogeneous) on the kinetics of gas-particle partitioning to be studied.

These data provide insights that can improve the representation of SOA phase state, hygroscopic response and organic partitioning, potentially refining our ability to predict the evolution of organic mass in, for example, regional transport models.

Growth of Atmospheric Clusters by Organic Vapors: Resolving the Growth Mechanism. JENNI KONTKANEN, Tinja Olenius, Markku Kulmala, Ilona Riipinen, *University of Helsinki*

New particle formation (NPF) is a significant source of atmospheric aerosol particles. According to current understanding, the key compounds in NPF are sulfuric acid, bases (e.g. ammonia and amines) and oxidized organic compounds. Therefore, there is a need for a robust physical description of NPF involving these compounds. One of the mechanisms suggested to depict this process is the nano-Köhler theory, which describes the activation of inorganic clusters to growth by condensation of a soluble organic vapor. In this work, we use molecular-resolution cluster kinetics simulations to investigate if the nano-Köhler theory is able to describe the growth of atmospheric molecular clusters.
We simulated the time-development of atmospheric cluster concentrations starting from vapor monomers up to clusters with mass diameter of ~3 nm by solving the discrete general dynamic equation for each cluster. The simulated systems involved two model compounds: a quasi-unary sulfuric acid–base mixture and an oxidized organic compound. In most simulations, the properties of a sulfuric acid–dimethylamine mixture and a representative low-volatile organic compound were used for the inorganic and organic vapors. We performed several simulation sets to investigate the effects of the volatilities and concentrations of the organic and inorganic vapors on the dynamics of the cluster population. From the simulated cluster concentrations, we determined the contributions of different vapor monomers and clusters to the growth over selected threshold sizes. We also determined the apparent cluster growth rates (GR) using the method that is applied for measured particle size distributions.
We found that the dominant cluster growth mechanism is determined by the organic vapor saturation ratio (S_{ORG}) and the ratio between organic vapor and sulfuric acid concentrations ($C_{\mathrm{ORG}}/C_{\mathrm{SA}}$). When S_{ORG} = ~4–40 and $C_{\mathrm{ORG}}/C_{\mathrm{SA}}$ = ~10–10000 nano-Köhler type behavior is observed: the organic vapor starts to contribute to the growth after a certain size is reached. With lower S_{ORG} and $C_{\mathrm{ORG}}/C_{\mathrm{SA}}$, sulfuric acid dominates the growth at the studied sizes, while with the larger values the organic compound dominates.
We compared the cluster activation size determined from the simulations to the predictions by the nano-Köhler theory and found that the two values can differ significantly. Thus, the nano-Köhler theory cannot be readily used to determine the cluster activation size. On the other hand, cluster GRs were often observed to start to increase around the activation size determined from the simulations. However, other dynamic processes, such as varying vapor concentrations, can also cause a similar increase in GR.

5AP.3

Effect of Temperature on Evaporation of α-Pinene Secondary Organic Aerosol. ZIJUN LI, Angela Buchholz, Olli-Pekka Tikkanen, Eetu Kari, Liqing Hao, Taina Yli-Juuti, Annele Virtanen, *University of Eastern Finland*

Volatility of secondary organic aerosol (SOA) constituents governs their partitioning between gas and particulate phase. Current studies have reported slower SOA evaporation than expected from Volatility Basis Set (VBS) parametrizations, suggesting considerable impacts from particle-phase diffusion and from condensed phase reactions (e.g. oligomer degradation). Aerosol measurements have revealed that lower temperature can significantly hinder molecular diffusion and suppress oligomer decomposition. Given the importance of these processes on SOA evaporation, investigations on SOA evaporation at low temperature are needed.

Here, evaporation of α-pinene photooxidation (αpinOH) and ozonolysis (αpinO_3) SOA was examined under a range of relative humidity (RH), both at warm (20 °C) and cold temperature (10 °C). Briefly, αpinOH and αpinO_3 SOA was generated using an oxidation flow reactor and then selected by two parallel Nano-DMAs with open loop sheath flow. After that, a sample flow of 80-nm SOA was either led directly to the instruments via a bypass line or fed into two 100-L Residence Time Chambers (RTCs). Short residence time data was obtained by varying the bypass tube length, while intermediate and long residence time data were collected from the RTCs during the filling period and in ~1h intervals after SOA filling, respectively. Aerosol characterization was conducted by a Scanning Mobility Particle Sizer (SMPS) and a High Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS). Size selection, evaporation and size change measurement were conducted in the temperature and RH controlled environment.

Evaporation of α-pinene SOA was hindered at lower temperature. This is consistent with the temperature dependence of saturation vapor pressures, but it may additionally suggest a temperature effect in the diffusion limitations in SOA particle bulk and the degradation of oligomers. Different evaporation behavior was observed for αpinOH and αpinO_3 SOA. This different volatility distribution most likely stems from a change in the particle chemical composition which is not represented by the very similar O:C ratio derived for the two SOA types. In addition, a kinetic-based evaporation model, coupled with Clausius–Clapeyron relation, was employed to reproduce the observed evaporation and derive the enthalpy of vaporization. These simulations showed that the derived enthalpy of vaporization was higher than the typical values assumed (30–40 kJ/mol) in global aerosol models.

5AP.4

Effect of Particle Charge on Aerosol Dynamics in Teflon Environmental Chambers. SOPHIA CHARAN, Weimeng Kong, Richard Flagan, John Seinfeld, *California Institute of Technology*

Data from environmental chambers are instrumental to understanding the chemistry of the atmosphere and aerosol formation. A common experiment in atmospheric chambers involves determination of the secondary organic aerosol (SOA) yield, the ratio of the mass of aerosol formed to that of a precursor vapor reacted. Since measurements of the amount of aerosol formed in such an experiment can be carried out only on suspended particles, one must account for particles deposited onto the chamber walls throughout the duration of an experiment to obtain an accurate assessment of SOA yield. The effects of particle charge on the aerosol dynamics within a chamber have long been a source of concern.

Here, we provide a procedure for diagnosing the extent to which particle charge contributes to particle dynamics within an environmental chamber. By tracking the preferential deposition of positively charged particles; by comparing experiments carried out under standard, humid, and highly statically charged conditions; and by performing two-parameter optimizations for the chamber eddy-diffusion coefficient and the average magnitude of the electric field, the effect of charge on the rate of particle wall deposition is isolated. A combined experimental and computational method is also developed for determining values for the eddy-diffusion coefficient and the average magnitude of the electric field within a FEP Teflon chamber. To fully account for the effects of charge on particle dynamics, studies of the effect of air ion concentration on the rate of particle coagulation over a typical experiment are performed and demonstrate, in general, that particle charge is negligible for characteristic chamber ion concentrations. Whereas the effect of particle charge on aerosol dynamics in an environmental chamber must be addressed for each specific chamber, we demonstrate experimentally that for the Caltech Environmental Chamber, charge effects on the rate of particle wall deposition are negligible.

5AP.5

Formation and Evaporation Kinetics of Organic Aerosol from Oxidation of Precursor Mixtures by the Nitrate Radical.

THOMAS BERKEMEIER, Masayuki Takeuchi, Gamze Eris, Michael Walker, Brent Williams, Nga Lee Ng, *Georgia Institute of Technology*

Formation of Secondary Organic Aerosol (SOA) was investigated at the Georgia Tech Environmental Chamber (GTEC) facility from separate, simultaneous and sequential oxidations of the precursors α-pinene and limonene with the nitrate radical (NO3).

For the detailed characterization of nitrated and non-nitrated reaction products in the gas and particle phases, GTEC was equipped with a High-Resolution Time-of-Flight Chemical Ionization Mass Spectrometer (HR-ToF-CIMS) coupled with a Filter Inlet for Gases and AEROsols (FIGAERO) as well as a HR-ToF-MS with the Volatility and Polarity Separator (VAPS)[1]. Aerosol formation was initiated at low temperatures of 5 °C and evaporation of product species monitored during step-wise heating to 42 °C. α-pinene and limonene SOA showed distinct evaporation patterns upon increase in chamber temperature.

The measurement data is analyzed using a novel kinetic modelling approach that utilizes a kinetic multi-layer model to describe the coupling of mass transport and chemical reactions in complex multiphase reaction systems. Special attention was given to gas-phase chemistry, vapor wall loss, diffusion in the particle bulk and temperature-dependent gas-particle partitioning of reaction products. The model simulations, along with FIGAERO-CIMS and VAPS-MS data, allow for distinction of the volatility distributions of nitrated and non-nitrated reaction products. We present evidence for kinetic limitations in the evaporation of organic material and a phase transition during the heating process. A semi-explicit chemical mechanism is presented that represents the experimental data and simplifies the Master Chemical Mechanism (MCM)[2] for the use in complex modelling applications. The chemical mechanism was generated using the Monte-Carlo Genetic Algorithm (MCGA)[3] as global optimization tool.

5AP.6

Air Ions – the Key in Understating Features in the Surface Atmospheric Electric Field in Relation to Aerosol Processes in the Lower Atmosphere. XUEMENG CHEN, Susana Barbosa, Antti Mäkelä, Jussi Paatero, Veli-Matti Kerminen, Tuukka Petäjä, Markku Kulmala, *University of Helsinki, Finland*

Under fair weather conditions, an electric field in the order of 100-150 Vm^{-1} exists in the Earth's atmosphere (e.g. Tinsley 2008). It was shown based on averaged data that the fair-weather electric field follows an alike diurnal pattern, known as the Carnegie curve, in different measurement locations around the globe (e.g. Harrison 2013). The global variations in thunderstorm activities have been believed to be the cause of this diurnal behaviour in the Carnegie curve (Whipple 1929), following the proposal of the global circuit concept by C. T. R. Wilson (Wilson 1921). In the global circuit concept, the Earth's surface and the ionosphere serve as the two electrodes of a capacitor that gets recharged by lightning activities while leaks under fair weather conditions through the flow of air ions.

Air ions are created by ionising radiation. In the lower atmosphere, air ions interact with aerosol particles. Atmospheric new particle formation, for instance, is one of the main aerosol processes that significantly changes the number size properties of air ions (Kulmala and Kerminen 2008). Air ion properties are altered by aerosol processes whereas the presence of air ions modifies atmospheric electric field. Investigations have been dedicated to understand the relations of air ions to aerosol processes and to atmospheric electric properties, respectively. Yet, there is little effort put in studies characterising the connection between atmospheric electricity and aerosol processes. To understand how atmospheric electric field varies with aerosol processes, air ions, being the medium connecting atmospheric electric properties and aerosol processes, are the paramount parameter.

During June-November, 2017, a measurement campaign was carried out at Hyytiälä SMEAR II station (61°51′N, 24°17′E, 181 m above sea level), which situates in a boreal forest in southern Finland (Hari and Kulmala 2005). We measured atmospheric electric field together with soil radon concentration, atmospheric radioactivity as well as air ion and aerosol number size distributions. The number size distribution data of air ions and aerosol particles is part of the routine measurement system at the station. Moreover, the station also provides access to meteorological parameters to further assist our analysis.

In the presentation, we will focus on features in electric fields in relation to aerosol processes, such as atmospheric new particle formation and wet scavenging. Our preliminary results showed that aerosol formation processes introduce variations in the fair-weather atmospheric electric field that blurs the Carnegie pattern and the washout of airborne radon progeny along with the wet scavenging of aerosol particles can result in a temporary increase in air ion production that modifies atmospheric electric field. With the advantages of our air ion and aerosol measurements, we will elucidate how air ion dynamics are reflected in patterns in the atmospheric electric field in relation to aerosol processes.

Fragmentation of Ionised Atmospheric Clusters inside a Mass Spectrometer. Monica Passananti, EVGENI ZAPADINSKY, Juha Kangasluoma, Nanna Myllys, Michel Attoui, Hanna Vehkamäki, *University of Helsinki*

The development of Mass Spectrometers (MS) as the Atmospheric Pressure interface Time Of Flight (APi-TOF) and the Chemical Ionisation APi-TOF (CI-APi-TOF) has revolutionised the study of new atmospheric aerosol particle formation. These instruments are able to detect molecules and small clusters, which are involved in the first stages of new particle formation, even at environmental low concentration. However, clusters' binding energies are much weaker compared to molecules; hence they can undergo transformations (fragmentation and/or evaporation) inside a MS easier than molecules. Correct accounting of collision induced cluster fragmentation (CICF) is of vital importance for retrieving the initial cluster distribution obtained in the experiments. Therefore, we decide to carry out a systematic study on the fate of clusters inside the APi-TOF and to develop a model to predict the fragmentation of clusters inside the mass spectrometer.

To investigate the fate of clusters inside the APi-TOF we combined it with a high-resolution Differential Mobility Analyser (DMA). The DMA allows us to measure the clusters size and separate them based on their size. Injecting into the APi-TOF only a mono-mobile size ions distribution it is easier to understand the fate of clusters inside the instrument because only one kind of clusters is studied at a time. We analysed sulphuric acid clusters produced by ElectroSpray Ionisation (ESI) and we focused our study on sulphuric acid trimer fragmentation inside the APi. This latter is made by three vacuum chambers (SSQ, BSQ and PB) where an electric field is applied to guide the ions through the interface. We evaluated the effects of the voltages applied to SSB, BSQ and PB chambers without changing the radio frequencies.

We developed a model to describe the CICF inside the APi. In this model, the charged clusters move through the APi under applied constant and uniform electrical field (defined by the tuning of the instrument). We consider each cluster individually and its trajectory is simulated as a random process. The clusters can be affected by energy transfer at collisions with residual carrier gas molecules and following fragmentation. The probabilities governing the energy transfer and the cluster fragmentation are based on level densities of the clusters and the products of fragmentation calculated by quantum chemical methods. After simulating the trajectory (and the fate) of a big enough number of clusters we calculate the proportion of the fragmented clusters.

The results are very promising, we have observed by the experiments and we confirm it with the simulations that the clusters are mainly fragmented at the interface between the first (SSQ) and second (BSQ) chambers. In this area, the pressure is low enough for the charged clusters to be considerably accelerated under electric field and the same time is still high enough for the clusters to experience collisions with the carrier gas molecules. The collisions induce transferring of the cluster translational energy to rotational and vibrational ones leading to clusters' fragmentation in some cases. We have observed good agreement between the experiments and the model. The development of this model and its validation by laboratory experiments is crucial to correctly interpret the experimental data obtained by APi-TOF instruments for simulating the atmospheric processes. It advances both understanding of the process of the new atmospheric aerosol particles formation and developing of the instruments.

Using Droplet Microfluidic Wells to Study Thermodynamics, Morphology, and Phase of Single Aqueous Aerosol Droplet Systems. Lucy Nandy, CARI DUTCHER, *University of Minnesota, Twin Cities*

Measurements of phase and phase change events in chemically complex aqueous droplets provide valuable information for understanding the dynamic processes in these complex micro-environments. For example, atmospheric aerosol droplets regularly undergo phase changes including liquid-liquid phase separation and crystallization. The phase and mixing state of the aerosol has profound effects on particle morphology, species uptake, equilibrium partitioning, activation to cloud condensation or ice nuclei, and optical properties. Many factors play a role in determining if a droplet will liquid-liquid phase separate, as well as its resulting orientation or morphology of the two phases, such as temperature, relative humidity, and chemical composition of the respective phases. In this work, single atmospheric aerosol droplet chemical mimics are generated in microfluidic channels and stored in passive traps until dehydration to study the influence of relative humidity and water loss on phase behavior. The solution volume of the droplet trapped changes with respect to time, and is calculated by image analysis and correlated with the concentration of the solution to determine water activities at each time interval. The research will help determine mixture liquid-liquid phase separation and efflorescence events of droplets that include presence of other dissolved components and tend to decrease the water activity. The measurements will also be used to parameterize statistical thermodynamic modeling for predictions of thermodynamic properties of aqueous aerosols as a function of relative humidity.

Off-line Analysis of Cloud Water Samples compared to On-line Measurements of Below-Cloud Aerosol Composition: Inferring Cloud Processing Impacts on Organic Aerosol. SARA LANCE, Jie Zhang, Amy Christiansen, Annmarie Carlton, Paul Casson, James Schwab, *ASRC, University at Albany, SUNY*

Aqueous chemical processing within cloud and fog water has been identified as a key process in the formation of secondary organic aerosol (SOA) mass, which is found abundantly throughout the troposphere. Yet, significant uncertainty remains regarding the organic chemical reactions taking place within clouds to produce SOA and the conditions under which those reactions occur.

Routine long-term observations from the Whiteface Mountain (WFM) Research Observatory in upstate NY provide a broad regional view of air quality, where important historical measurements of secondary aerosol formation have been made, focusing on inorganic chemical reactions leading to acid rain deposition. The site is also well-suited for the study of SOA formation within clouds, as the summit of WFM intercepts clouds roughly 50% of the time throughout the summer and the site is deep within the Adirondacks where it is generally undisturbed by local sources. An NSF-funded workshop in Sept 2016 brought together key researchers at WFM to lay out the most pertinent scientific questions relevant to heterogeneous chemistry occurring within fogs and clouds. The workshop culminated in a plan to coordinate chemical analyses of cloud water samples specifically focusing on the organic component. Workshop participants also recommended a pilot study at the WFM to better characterize the meteorological conditions, airflow patterns and clouds intercepting the site for future intensive field operations.

This talk will highlight observations from the 2017 pilot study at WFM, with a focus on off-line chemical analyses of cloud water samples collected at the summit and comparisons to on-line measurements of the below-cloud aerosol composition.

A Study on Light Absorbing Carbon Soot Particles and Their Speciation over Semiarid Region of Indo-Gangetic Basin.

PRATIMA GUPTA, Ashok Jangid, Ranjit Kumar, *DEI, Dayalbagh, Agra, India*

The light absorbing soot particles has high global warming potential after green house gases and affects climate change. The absorbing properties of soot particles are influenced by the nature of surrounding particles. Hence, speciation of carbon soot particles has been done using aethalometer and SEM-EDX over semiarid region of Indo-Gangetic basin. The average mass concentrations of carbon soot particles were found to be 7.4±3.4 μgm^{-3}. The highest soot particle concentration has been seen in winter followed by post-monsoon, summer and monsoon. It may be due to variation in source strength and meteorological conditions. The anthropogenic sources viz., biomass/fossil fuel burning enhances the concentration during winter. The concentration of carbon soot particle at shorter wavelength (UV range) to longer wavelength (IR range) has shown large variations. The monthly spectral variation of soot particles with the fraction of different types of soot particle have been shown at seven wavelengths (370-950 nm). The monthly spectral variation shows the higher concentration of carbon soot particle at 370 nm (UVPM). The variations of aerosol light absorption with wavelength have been extended from the near-ultraviolet to the near infrared. Brown carbon (UVPM370) consists of light absorbing organic matter originates from biomass burning. The daily average of UVPM at 370 nm was 9.3±10.2 µg m^{-3}. The daily average of blue carbon at 440 nm is 7.6±7.8 µg m^{-3}. The blue carbon at 440 nm is a certain classes of organic compounds (such as polycyclic aromatic hydrocarbons). The soot particles at 520 nm are known as green carbon. The daily average of yellow carbon at 590 nm is 7.2±8.3 µg m^{-3}. SEM-EDX analysis revealed the most abundant group of particle of soot carbon is influenced by tobacco smoke. The daily average concentration of RC660 is 6.7±3.7 µg m^{-3}. Hematite mineral dust (Fe_2O_3) has absorption bands in the red region of the spectrum and hence the abundance of this material can increase response of 660 nm channel. Carbon soot particle also gives significant response at IR-II (950 nm). Certain inorganic compounds may show the onset of molecular absorption in the near-infra-red: their presence may increase the apparent result in the 880-nm and 950-nm. Light absorption by aerosols collected in biomass burning smoke varied more strongly with wavelength than aerosols dominated by motor vehicle emissions. The SEM-EDX analysis of carbon soot particles reveals the confirmation of the various elements which are emitted from various sources like burning of biomass and fossil fuel, tobacco smoke, dust particles, sand particles, vehicular emission and mineral dust. This analysis also reveals the confirmation of carbon soot particle associated with the various other elements viz., C, Al, Si, K, Na, F, Ca, Fe, Zn, Cu, etc.

Temperature Matters More than Concentration: CCN-activation of Soot after Exposure to Ozone under Atmospheric Conditions. FRANZ FRIEBEL, Amewu Mensah, *ETH Zürich*

Freshly emitted soot particles are known to be poor cloud condensation nuclei (CCN), but from atmospheric measurements it can be deduced that a significant fraction of soot particles act as CCNs. One process which might contributes to this discrepancy is the heterogeneous oxidation of soot particles. Soot particles have an average atmospheric lifetime of one week. During this time, they are exposed to different aging processes, like oxidation with ozone, which might change how the soot particles interact with water.

The investigation of those processes is an experimentally challenging task, due to the long time span which should be covered. Many studies were conducted in which soot was treated with oxidants at concentrations exceeding the atmospheric average by a factor of 1000. This approach reduces the needed observation time, but in case of ozone it does not consider the non-linear reaction kinetic with soot.

In Winter 2017/18 we conducted a lab campaign at ETH Zurich where we investigated the reaction of ozone with soot particles, under atmospheric conditions. With the CSTR-approach we could observe 100nm size selected soot particle up to 16 h. The particles were exposed to Ozone concentration between 22 and 220 ppb at a temperature range of 5 to 35°C. We measured the CCN-activity at different super saturations between 0.3% to 1.4 %.

It was found, that an increase of the ozone concentration at 25°C, by a factor of 10 (from 22 to 220ppb) lead to a reduction in the activation time by factor 1.8 (from 7h to 3h:50min at 1.0 % super saturation). A temperature increase from 5°C to 35°C at a constant Ozone concentration of 200 ppb lead to an reduction of the activation time by factor 5. Our results indicate, that for an assessment of the cloud formation potential of soot particles the ambient temperature should be considered as much as the ozone concentration.

According to the literature, the reaction kinetics can be best described by the Langmuir-Hinshelwood-mechanism, where the reaction is initiated by the adsorption of an Ozone-monolayer. The speed of the reaction is approximately proportional to concentration of ozone adsorbed on the soot surface, but not to the gas phase concentration. [1] This agrees well with our observations. After exposing soot particle several minutes to different Ozone concentrations, the particle diameter increased by 3% and the particle mass by 20%, but remained almost constant during further exposure. Additionally the ozone concentration in the gas phase had little influence on the activation time.

Based on our temperature experiments we calculated an activation energy of 40 kJ/mol for the time limiting step causing CCN-activation. This value is in accordance with previous findings and indicates that the limiting reaction step for the CCN-activation is a conversion of physisorbed Ozone into organic Ozonides. [2]

Characterization Of Laser Derivatized Soot Nanostructure Towards Identifying Its Source. MADHU SINGH, Randy Vander Wal, *The Pennsylvania State University*

Soot source identification by characterizing nanostructure of the laser annealed material is based on the premise that soots originating from different combustion sources differ in their nanostructure because of the variation in formation conditions. Conditions of temperature, pressure, fuel, fuel-air-ratio, fuel-air mixing are specific to each source during combustion and differ between sources. Thus, soot produced from different sources will vary to reflect its formation conditions. TEM imaging with the application of image analysis algorithms is used to quantify nanostructure parameters. When sufficiently distinct, the contrasting nanostructure can identify the soot origin. Where similar nanostructure or poorly contrasted nanostructure is observed, subtle differences may be magnified by laser derivatization to enhance lamellae recognition and quantification. Derivatization is a process by which a compound is chemically changed, producing a new compound that has properties amenable to a particular analytical method. Laser derivatization is used here in a similar manner to enhance subtle differences in soot nanostructure upon laser heating. Due to the extremely rapid heating (~ 5 nanoseconds to reach 3700°C) and cooling (microsecond) timescales observed when soot is irradiated with a Q-switched laser pulse, soots anneal incompletely due to apparent kinetic limitations on these timescales. Convolved with these changes are small differences in initial nanostructure and composition that become magnified by the fast heating and rapid quenching.

Source identification is important to pollution receptor models that require knowledge of source contributions at receptor sites. In this study soot samples from known sources are imaged via transmission electron microscopy (TEM) before and after laser heat treatment. Image processing algorithms quantify nanostructure characteristics including fringe length, fringe tortuosity, fringe spacing, stacking and curvature for nascent and laser heated soot. These metrics collectively comprise the identification marker or “fingerprint” for soot. Unknown samples can then be compared against information available from existing samples to identify its source or have a close estimate of what the source may be, both qualitatively and quantitatively. Quantitative comparison for identification uses statistical analyses. By this approach, laser derivatization uses the changed soot nanostructure post laser heat treatment to identify the soot source.

Effects of Uneven Coating on the Absorption Enhancement of Soot Aggregates. WILLIAM HEINSON, Rajan K. Chakrabarty, *Washington University in St. Louis*

Soot Aggregates (SAs) in the atmosphere significantly influence the earth's radiation balance, visibility, and public health. They are formed from high-temperature, incomplete combustion of fossil fuels and biomass burning via diffusion limited cluster-cluster aggregation (DLCA) of spherical monomers. SAs can contain a significant amount of non-refractory compounds coated on to its surface which may enhance the SA's natural light absorptive properties through "lensing" effects. Depending on the strength of the lensing effect, the absorption enhancement can be up to a factor of 3. We studied how the wetting of the coating material onto the SA's affects the absorption enhancement. A Monte-Carlo method was employed to simulate the affinity of the coating materials to wet the SAs. The coated SAs' light absorption properties were then calculated using a discrete dipole approximation (DDA) algorithm. In many climate models, SAs are approximated by an equivalent-mass core-shell spherical model due to the ease of calculating optical properties using Lorentz-Mie theory. Keeping this in mind, we calculated the optical properties of core-shell spheres equivalent in mass to our coated SAs. Comparisons of the core-shell spheres with the coated aggregates showed that the mass absorption cross-sections (MAC) were significantly underestimated in the core-shell approximation when the coating uniformly wetted the SAs. When the coating was not evenly applied to the SAs, the enhancement could be significantly reduced.

Characterization of a Novel Miniature Inverted Burner for Soot Particle Generation. Alireza Moallemi, Mohsen Kazemimanesh, JOEL CORBIN, Gregory Smallwood, Jason S. Olfert, Prem Lobo, *National Research Council Canada*

Carbonaceous particles generated by incomplete combustion can absorb light remarkably well and have a strong climate forcing potential. Additionally, there are substantial concerns about the negative effect of combustion generated carbonaceous particles on public health. The research community employ various types of combustion-based aerosol generators, to study the properties of these particles in laboratories. One such combustion-based aerosol generator is the inverted burner developed by Stipe et al. (2005), which has been proven to be a robust source for soot particle generation and was employed in various studies involving soot particle characterization and instrument calibration. Although this burner was extensively employed in lab-based studies, the relatively large dimensions of the burner make its handling difficult and limit its use in various applications, such as field calibration of aerosol

The miniature inverted burner (“mini-inverted burner”) is a modified design in which the size of the inverted burner has been substantially reduced. The main advantages of this burner are its portability, simplicity, low fuel consumption, and relatively low cost per unit compared to the other commercial portable soot generators. In this study, the general performance of the mini-inverted burner was examined using two different fuels: propane and ethylene, and the tests were performed at various air and fuel flow rates. The capability of the burner to generate particles in a stable and repeatable manner was investigated and its ability to produce particles with a variety of sizes and concentrations was demonstrated. In addition to the particle size distribution, other properties of generated aerosol particles, such as optical properties and the amount of elemental carbon (EC) and organic carbon (OC), were measured. This study shows that the mini-inverted burner is capable of generating particles with a verity of mode sizes (120 nm to 200 nm), and number concentrations ($\sim 5\times10^5$ cm^{-3} to $\sim 3\times10^6$ cm^{-3}). Additionally, in some set-points the elemental to total carbon (EC/TC) ratio of the generated soot particles were found to be larger than 80%, which makes this burner ideal for producing carbonaceous particles with high EC to OC content.

UV-visible Absorption Spectrum of Laboratory-generated Soot Particles. Al Fischer, Taylor Helgestad, Lindsay Renbaum-Wolff, Andrew Lambe, Arthur J. Sedlacek, Christopher Cappa, Andrew Freedman, Timothy Onasch, Paul Davidovits, GEOFFREY SMITH, *University of Georgia*

The absorption by soot particles generated from a methane inverted diffusion flame burner was measured across the UV-visible region of the spectrum. Two cavity ringdown (CRD) laser photoacoustic spectrophotometers (PASs) (405 nm and 532 nm), a lamp/laser PAS (301 nm - 662 nm), and a cavity attenuated phase shift single-scattering albedo monitor (CAPS PMSSA) (630 nm) were employed to measure absorption of suspended particles at a total of 10 different wavelengths. In general, very good correlation between the instruments was found with correlation coefficients, R^2, of at least 0.93. Mass absorption coefficients (MACs) were calculated from measurements of particle mass made using a single particle soot photometer (SP2) and a centrifugal particle mass analyzer (CPMA), resulting in an interpolated value at 550 nm of 7.54 (± 0.43) m^2/g. A power law function with the commonly assumed values of absorption Ångström exponent (AÅE) = 1.0 and $MAC_{550} = 7.5\ m^2/g$ is found to describe the visible part of the spectrum well, but it underestimates UV absorption where the discrepancy is as high as 22%. A power law fit to the entire spectrum yields an AÅE of 1.21 (± 0.08), but a systematic increase in AÅE with decreasing wavelength was observed. It is shown that Mie theory with particles represented by volume-equivalent spheres is not adequate to reproduce the shape of the spectrum regardless of refractive index used. On the other hand, the use of a modified Rayleigh-Debye-Gans approximation with a single, wavelength-independent refractive index is able to do so, though it underestimates MAC values by 25-35% depending on the value of the refractive index used.

5CA.8

Optical Properties and Radiative Forcing of Fractal-like Aggregates of Tar Balls from Wildfire Smoke Plumes. JANARJAN BHANDARI, Swarup China, Giulia Girotto, Barbara Scarnato, Kyle Gorkowski, Allison Aiken, Manvendra Dubey, Claudio Mazzoleni, *Michigan Technological University*

Tar balls (TBs) are carbonaceous spherical particles present in biomass burning smoke. In most studies, based on electron microscopy, TBs are typically reported as individual spheres (mostly ~100-300 nm in diameter). TBs absorb radiation in the UV-visible part of the solar spectrum, and therefore, they are considered a component of brown carbon aerosol. The TB optical properties reported in the literature are highly variable which in turn, make their radiative effects highly uncertain. TBs are typically studied as individual spheres. However, in a recent study, we report an abundance of fractal-like aggregates of TBs from the White-water Baldy complex fire. The optical properties of an aggregate of spheres depend on various factors such as the sphere size, the number of spheres, the refractive index, and the wavelength of the incident light. Therefore, we numerically simulated the optical properties of these aggregates using T-matrix. To determine the significance of the aggregation, we compare the T-matrix results with Lorenz-Mie simulations in two scenarios: 1) Each TB in an aggregate act as an independent sphere, so the cross sections are equivalent to the cross-section of one TB times the total number of TBs present in the aggregate (Mie-N-spheres simulation); this is equivalent to compare an aggregate with its independent components. 2) The entire aggregate is approximated as a volume equivalent single sphere of the same volume as the aggregate (Mie-VER simulation).

We calculated absorption and scattering cross-sections, single scattering albedo and hemispheric upscatter fraction of TBs for each simulation at 550 nm for several different values of indices of refraction including extreme values reported in the literature. To study the impact of number and size of spheres, and wavelength, we performed sensitivity analyses by varying the number of spheres (N = 8, 16 and 32), at five different wavelengths (350 nm, 550 nm, 750 nm, 950 nm and 1150 nm) and for three radii of 50 nm, 75.25 nm and 100 nm. Finally, we estimated the direct radiative forcing (DRF) for each simulation at 550 nm and for high and low surface albedo of 0.8 and 0.06, respectively; assuming an arbitrary TBs optical depth of 0.1.

Taking the T-Matrix as a reference, our simulations show that for single scattering albedo and upscatter fraction, the percent differences between the T-Matrix and Mie-N-spheres are large, up to ~40% and 120%, respectively. Similarly, the differences between the T-Matrix and Mie-VER are up to ~20% and 40%, respectively. The DRF from the T-Matrix differs by more than -1 Wm^{-2} from the Mie-N-spheres, while the DRF for T-Matrix exceeds that of Mie-VER by up to ~ +5 Wm^{-2}, depending on the surface albedo.

Our simulations show that the optical properties and radiative forcing of TB aggregates are considerably different from those of individual TBs and aggregation should be accounted for in radiative transfer calculations.

5CD.1

Synergy between Power Plant and Vehicle Emissions Produce Aerosols Linked to Adverse Cardiovascular Outcomes.

RODNEY J. WEBER, Jenny P.S. Wong, Athanasios Nenes, James Mulholland, Armistead G. Russell, Dongni Ye, Stefanie Ebelt Sarnat, *Georgia Institute of Technology*

Multiple studies have linked adverse health effects to particulate metals. A recent epidemiological study from 1998 to 2013 based on hospital emergency department visits in metropolitan Atlanta found that among a range of PM2.5 components tested, water-soluble iron had the strongest estimated effect on cardiovascular outcomes (risk ratio per 20 ng/m3 increase in water-soluble iron is 1.012, with 95 percent confidence interval of 1.005 to 1.019)[1]. Other shorter term studies have shown that vehicle brake or tire wear and road-dust are a major source of iron in Atlanta[2]. Yet over the period of the epidemiological study, the water-soluble iron concentration time-series closely followed trends in sulfate concentration, not total iron. This included tracking both seasonal trends and dramatic changes in sulfate concentration due to specific emission reductions in coal-fired power plants in the past 10 years. To explain the observed trends, we explore the link between iron, sulfate and water-soluble iron through sulfate's influence on particle pH and liquid water content via model simulations spanning the period of 1998 to 2013. These results demonstrate the importance of atmospheric processing on aerosol toxicity and illustrate an unexpected health benefit of coal fired power plant emission reductions.

Tissue-Delivered Dose – Not Exposure Concentration – Allows Conversion of Toxicological Studies into Acceptable Human Exposure Limits. OTMAR SCHMID, *Helmholtz Zentrum Munchen, Comprehensive Pneumology Center*

Inhalation toxicology studies with aerosols using animal (*in vivo*) or cell-based *(in vitro*) models of the lung are technologically challenging and typically require advanced aerosol equipment for controlled exposure conditions. In spite of these efforts, conversion of these toxicological data into regulatory relevant recommendations for safe/acceptable human exposure limits is often not possible due to fundamental flaws in aerosol dosimetry.

Frequently, estimated worst case scenarios for human exposure levels are chosen as guidance for toxicological studies and “no-response” at these exposure levels is FALSELY interpreted as indicator for “safe” materials. However, not exposure levels but tissue-/organ-delivered dose is essential for reliably risk assessment. Moreover, the susceptibility of the toxicological model (cell/animal) relative to an equivalent human response has to be assessed carefully. For instance, in vitro cell-based inflammatory responses frequently occur at much higher equivalent dose levels than observed in animal models or humans. All of these issues have to be addressed for reliable risk assessment based on toxicological studies.

In this talk, the key factors linking exposure concentration in toxicological studies to equivalent human exposure concentrations and hence acceptable exposure limits are discussed. Essentially this requires careful consideration of the relationship between exposure concentration (external dose) and tissue-delivered dose (internal dose) which includes aerosol characteristics (size, density and shape) as well as geometry of the exposure system (e.g. lung morphology, geometry of cell exposure chamber), flow conditions (or respiratory conditions) and exposure time. As an example, an overview of currently available aerosol-cell exposure systems and suitable real-time dosimetry methods are presented (e.g. Quartz Crystal Microbalance).

Finally, the most difficult aspect of deriving acceptable exposure levels from toxicological studies is the assessment of model- and response-specific susceptibility factors. This issue will be elucidated by providing typical onset doses for various models and endpoints (cell-based, animal-based, acute/chronic response). These doses will be put into perspective by comparison with real world exposure scenarios in both urban and occupational settings.

This talk highlights the pivotal role of (normalized) tissue-/lung-delivered dose, preferentially in terms of surface area, for reliable risk assessment of inhaled particles. It also highlights important implications for the design of toxicological studies and the development of aerosol technology tailored towards the needs of health-effects studies.

5CD.3

A Novel Weighted Sum Method to Measure Particle Geometric Surface Area in Real-Time. LEO N.Y. CAO, David Y. H. Pui, *University of Minnesota*

This study reports the development of a novel method to measure the aerosol geometric surface area (GSA) concentration with a time resolution of a few seconds. In the method, the commercialized nanoparticle surface area monitor was used and slightly modified. The instrument responses under two different conditions were combined in a weighted sum (WS) fashion to correlate with the aerosol GSA concentration. We present the GSA concentration results and comparisons with well-known SMPS data in both laboratory testing and field measurement. For the laboratory testing, the two methods have a good agreement with a Pearson correlation coefficient of 0.9961; for the field measurements including the indoor and outdoor samplings, both methods agree well with each other. In addition, the new WS method is more stable in the clean indoor air and suitable for outdoor environmental sampling with a slight overestimation (125% of SMPS).

5CD.4

Is the Particle Deposition in a Cell Exposure Facility Comparable to the Lungs? ERWIN KARG, George A. Ferron, Sebastian Oeder, Ralf Zimmermann, *Helmholtz Zentrum München and Rostock University*

Biological endpoints from cell exposure experiments are often taken as indicators for health implications and for the impact of ambient aerosols on the lungs [1, 2]. The advantages of such experiments are their relatively short duration, good repeatability, suitable statistics and cost-effectiveness due to lab-scale facility dimensions. Additionally, with respect to the physical deposition processes, the exposure situation is supposed to be similar to the one in the lungs if particles stay airborne when provided to cells in an air-liquid-interface (ALI) system.

However, geometry and air flow rates in an ALI system deviate considerably from the ones in the human respiratory tract (RT). Computer models for particle deposition were developed [3-5] and are adopted here to mimic the exposure situation, to identify the differences and to characterize the deposition patterns in both ALI and RT. As cells from different parts of the RT can be used in an ALI system, a lung deposition software has to be applied which is able to model the regional deposition in the extra-thoracic, bronchial and alveolar region.

Runs of both ALI and RT model were performed for different particle size distributions, and their output was configured to provide the number of deposited particles per surface area (dose per area, DPA) of exposed cells in both the ALI and the RT regions. The built-in dichotomous human lung structure [6] in the RT model provides number, geometric diameter and length of the airway ducts and therefrom an estimate of their geometric surface area.

Results show the DPA in the ALI being 4-5 orders of magnitude higher than in the alveolar region, as the surface area in the deep RT is extremely high and the inhaled particulate matter is spread out over it. In the bronchial region, however, the DPA of the ALI is found to be higher by a factor of 2-10 only and cumulated deposition is therefore much better comparable. However, hot spots may be present in the airways as lung clearance occurs along defined paths and some locations are not well cleared. Additionally, particles are deposited merely according to aerodynamic processes, and being different in size and composition.

In conclusion, i) due to the high DPA, an ALI exposure experiment mimics the cumulated RT alveolar exposure of days; consequently, the experiment duration can be kept short and concentration can be kept low. And ii) if the DPA in ALI and RT should be comparable, cell lines from the bronchial or extra-thoracic region should be used as biological targets.

Optimization of DAVID Cell Exposure System for Toxicity Analysis of Nanoparticles at the Air-Liquid Interface. TREVOR TILLY, Ryan Ward, Jiva Luthra, Sarah Robinson, Arantzazu Eiguren Fernandez, Saber Hussain, Tara Sabo-Attwood, John Lednicky, Chang Yu Wu, *University of Florida*

Understanding the health effects associated with the inhalation of nanoparticles is critical for determining the risk they pose during occupational and environmental exposures. The many different types and variations of nanoparticles has made evaluating their toxicity burdensome by *in vivo* methods alone, and resulted in the development of many different in vitro toxicity analyses. Despite this development, the current existing methods of *in vitro* have drawbacks when evaluating occupational and environmental exposures of nanoparticles resulting from their fundamental properties. For instance, the process of collecting nanoparticles from the environment on filters and then later extraction in media for toxicity analysis in the laboratory can greatly alter the properties of the particles directly after emission, and subsequently alter their toxicity outcome. To remedy the incorporation of these particle transformations that can result from sample collection, air-liquid interface (ALI) exposure systems have been developed to deliver nanoparticles from aerosols directly to cells. However, deposition of nanoparticles on cells at the ALI may be skewed to a certain size range of particles because the aerosol methods of thermophoresis and electrostatic precipitation often utilized to increase deposition efficiency in these systems are dependent on particle charge and size. A new cell exposure system known as DAVID, Dosimetric Aerosol *in Vitro* Inhalation Device, was designed to improve the delivery of a broad range of nanoparticles through increased inertial force accomplished by amplifying particles as small as 10 nm to a uniform size of 3 µm by condensing water vapor onto the particle. With this technology, evaluation of the toxicity of nanoparticles was achievable with short exposure times by delivering a concentration of particles that met or exceeded the lowest observed adverse effect level. Custom cell culture supports were fabricated by 3D printing, functionalized by oxygen plasma corona for cell attachment, and sterilized with ethanol and UV. With the current setup, four cell membranes cultured at the ALI can be exposed simultaneously so that statistical analysis can be performed within each exposure trial. First, the delivery of clean air to the cell surface was optimized in DAVID to ensure that the flow rate would not cause adverse effect to the cells by drying them out. A flow rate of 2.1 L/minute/cm^2 was selected based on sampling recommendations, but resulted in a reduction of cell viability by 25% of control. Therefore, the flow rate was reduced to 1.4 L/minute/cm^2 and was found to maintain greater than 97% viability of the cells. The deposition of nanoparticles in DAVID was calibrated and determined to increase linearly with time from an uranine aerosol generated by a Collison nebulizer with a mean particle size of approximately 58 nm. The raw fluorescence of the collected uranine droplets on the membranes was measured and related to a calibration curve to determine the deposition mass concentration. Nanoparticle concentration in the nebulizer and dilution flow rate was directly related to the mass deposition of particles in DAVID, which resulted in a mass deposition ranging from 177 ng/cm^2 to 2.93 µg/cm^2 for exposures up to 20 minutes. Post optimization, the cells were exposed to CeO nanoparticles with mean diameter of 39.5 nm generated by the Collison nebulizer in the laboratory, and the delivered dose was assessed by inductively-coupled plasma mass spectrometry. The viability of the cells after exposure was assessed by lactate dehydrogenase assay (LDH) and related to the deposited dose of particles on the cells. Future studies to determine mechanistic nanoparticle-cell interactions at the ALI are the next step for the DAVID exposure system.

Oxidative Potential of Quinones in Simulated Epithelial Lining Fluid Alone and in Combination with Redox-Active Metals. KARSTEN BAUMANN, Marco Wietzoreck, Jake Wilson, Pourya Shahpoury, Steven Lelieveld, Haijie Tong, Ulrich Pöschl, Gerhard Lammel, *Max Planck Institute for Chemistry*

The human health risk posed by reactive oxygen species (ROS) produced from fine particulate matter ($PM_{2.5}$) components in epithelial lining fluid (ELF) of the deep lung is a matter of intense scientific interest (Lakey et al. 2016). In aerobic metabolism, oxidative stress can be exerted by excessive ROS comprised of free radicals such as O_2^-, OH, ROO, RO, and non-radical species such as H_2O_2 and O_3. Upon inhalation, many oxygenated and nitrated polycyclic aromatic hydrocarbons (NOPAHs) in airborne $PM_{2.5}$ may contribute to ROS formation, most effectively quinones, which form O_2^- by reactions involving the semiquinone radical. NOPAHs are found regularly in the ultra-fine fraction of $PM_{2.5}$, and can be emitted by incomplete combustion processes (e.g. from diesel engines and biomass burning) or formed in atmospheric photochemical processes. Quinones are known to trigger and maintain catalytic reaction cycles causing oxidative stress at the cellular level (Bolton et al. 2000). In assays addressing the so-called oxidative potential (OP), which is assumed indicative of ROS formation, different redox-active components of ambient $PM_{2.5}$, such as quinones or transition metals, esp. Cu, Mn, Fe, can cause synergistic or antagonistic effects (Xiong et al. 2017, Yu et al. 2018). However, this chemistry is not well understood yet.

In order to investigate each redox active species' OP individually and in combination, we developed an experimental setup representing extracellular conditions in the deep lung that allows reproducible loading of a simulated ELF, containing antioxidants, electrolytes, surfactants and proteins (Boisa et al. 2014). This SELF was refined by sterile filtration, in order to decrease bacterial impurity. Hydrophobic polystyrene latex (PSL) spheres with nominal 60 nm diameter are used to mimic transport of NOPAHs to the alveolar region. The PSL also enhance atomization of select NOPAH compounds dissolved in a mixture of organic solvent (ACN or DMSO) and ultrapure water. The generated particles are collected by continuously refluxed SELF in a mist chamber, and simultaneously on a quartz filter. Delivery and uptake kinetics of two nitro-PAHs and three oxy-PAHs, have been investigated.

The OP and ROS yield of the differently loaded SELF is determined by means of three acellular assays, in particular H_2O_2 formation (Sigma-Aldrich 2014), DTT depletion (Charrier & Anastasio 2012), and antioxidant depletion (glutathione and ascorbic acid). We present and interpret the results in light of possible synergistic or antagonistic effects. Ongoing modeling (Lakey et al. 2016) may benefit from insights gained.

A Semi-Automated System for Measuring the Reactive Oxygen Species (ROS) Catalyzed by Ambient Particulate Matter (PM) in a Dithiothreitol (DTT) Assay. HAORAN YU, Joseph Puthussery, Vishal Verma, *University of Illinois Urbana-Champaign*

The oxidative potential of ambient particulate matter (PM), i.e. the ability to generate reactive oxygen species (ROS) in the presence of a biological reductant, has been investigated for a long period of time. In our previous study, we found that dithiothreitol (DTT) could be used to indicate the oxidative potential of PM by measuring both consumption rate of DTT and generation rate of •OH. Although, the measurement of DTT consumption has already been automated, •OH measurement, which is a labor-intensive process, still employs a manual protocol, limiting the number of samples that can be analyzed in a day. To overcome this problem, we are developing a system for analyzing the oxidative potential of PM liquid extracts based on the DTT assay in a semi-automated mode. This system uses DTNB to determine the concentration of DTT, and terephthalate (TPT) to capture the •OH generated from the oxidation of DTT. An automated Kloehn control pump system with sample injection valve is used to automate the protocol. A liquid wavelength capillary cell (LWCC) and a Horiba spectrofluorometer are used for quantifying the DTT and •OH concentration, respectively. The system will be calibrated with pure substances (9,10-phenanthraquinone, PQ and 5-Hydroxy-1,4-naphthoquinone, 5-H-1,4-NQ) as the positive controls, and will be tested for its performance with the real ambient PM samples collected from an urban site. The detection limit, accuracy and precision of the system will be evaluated. The seasonal variability in the oxidative potential of ambient PM measured by this system will also be presented. Finally, we anticipate that system can be coupled to a PM sampling device to monitor the oxidative potential of ambient PM in real-time.

Lower Order Representations of Evolving Particle Size Distributions for Rapid Gas-Particle Mass Transfer Simulations during Electrostatic Precipitation. HEREK CLACK, *University of Michigan*

The range of particle sizes typically present in combustion flue gas complicates predictions of gas-particle mass transfer processes. This complexity is amplified within electrostatic precipitators where particle motion, abundance, and mass transfer characteristics are all size dependent. The present study illustrates the utility of replacing explicit representations of particle size distributions in simulations of electrostatic precipitators with an equivalent loading of monodisperse aerosols of diameter chosen to reproduce the same gas-particle mass transfer characteristics. Computational times are reduced by an order of magnitude using this approach, facilitating future incorporation of multiple particle types or heterogeneous chemical kinetics.

5CM.2

Development of Filter-free Particle Filtration Unit Utilizing Condensational Growth. Taejune Park, Miji Lee, Juwon Pyo, DONGGEUN LEE, *Pusan National University*

The public health impact of particulate matter in ambient air with a size of 2.5 µm or smaller (PM2.5) has been of great concern. It is well known that PM2.5 is much more harmful to human health than coarse particles. To remove PM2.5, most air purifiers on the market have been equipped with a high efficiency particulate air (HEPA) filter. Under the circumstances that generate PM2.5 aerosols at high concentrations such as during indoor cooking or in work places, HEPA-grade filters are neither durable nor applicable because of their high replacement cost. Thus, a large number of cooks and workers are exposed to intensive emissions of PM2.5 without proper filtration. In this paper, we introduce two conceptual designs to remove PM2.5 without HEPA filters. A key idea of the first approach is to use the condensational growth of particles. Once the particles have grown to a few micron, they are much easier to remove because of their increased inertia. Based on this, we developed the first prototype of a filter-free particle filtration unit consisting of an air saturator (equipped with water spray nozzles), a condenser in which humid air is cooled down to a supersaturation state and thereby allows particles to grow by condensation, and a multi-nozzle-impactor assembly for collecting the grown particles downstream of the condenser. We started with a small-scale model, and then demonstrated that a large-scale prototype could remove organic, inorganic, and metallic ultrafine particles with a collection efficiency of larger than 80% at a volume flow rate of 50- 92 L/s.

5CM.3

A Corona Charger System for Improving Particle Filtration Efficiency of Flue Gas Scrubbers and Cyclones in Small Biomass-fired Boilers. HEIKKI SUHONEN, Ari Laitinen, Miika Kortelainen, Arunas Mesceriakovas, Hanna Koponen, Petri Tiitta, Pasi Yli-Pirilä, Jorma Jokiniemi, Olli Sippula, *University of Eastern Finland, Kuopio, Finland*

New flue gas particulate matter filtering technologies are needed due to upcoming new regulations for small and medium -scale biomass combustion appliances in Europe. The Ecodesign directive will affect combustion appliances with a rated heat output of 500 kW or less and the Medium Combustion Plant (MCP) directive boilers of 1-50 MW output. Existing commercial flue gas cleaning techniques are often either too expensive compared to the total costs of small boilers, provide too much pressure loss and maintenance, or are not efficient enough to meet the new regulations. Therefore, new methods for cost-efficient particulate filtering need to be developed. For existing boiler units the utilization of electrical charging of flue gas particles upstream of heat exchangers or in front of existing particulate filters is an interesting low-cost approach to improve the filtration efficiency of particles.

A single needle corona charger (Laitinen et al. 2016), was used together with a pilot-scale condensing heat exchanger (CHX) (Grigonyte et al. 2014) and a cyclone, which were installed into a wood chip fired combustion reactor simulating automatic grate boilers. The single needle corona charger is mechanically simple and can be introduced into the flue gas in existing devices and shielded against contamination, while the CHX and cyclone provide the collection surface and additional cleaning mechanism. The effects of charging temperature and different combustion conditions on the charger performance were investigated by changing the charger position in the combustion reactor and using it with different fuel qualities.

Total particle mass emissions were reduced by >80 % with the combination of charger and CHX while the combination of the charger and cyclone setup was slightly less efficient. Particle number reduction efficiency varied between 30 % and 70 %, because the usage of the corona charger produced a nucleation mode below particle size of 30 nm that was highly dependent on the charging temperature and voltage. Particle mass was measured also from between the charger and CHX, for estimating the reduction efficiency of the CHX alone. PM1 emissions were reduced in the CHX by 30-40 % when particles were not charged and 60-70 % when particles were charged before the CHX. Chemical analysis of the condense water from the CHX support the results as enhanced concentrations of typical components of wood combustion fly ash were also found in the water.

The results indicate that a simple corona charger system can provide a feasible particle filtration system together with a condensing heat exchanger, wet scrubber and/or a cyclone to achieve the upcoming new regulations. The system is best suited for small-scale boilers but can be upscaled by increasing the number of corona chargers.

This work was funded by the European Regional Development Fund, within the Pyreus project.

Correlation Between Corona Current Distribution and Collection of Sulfuric Acid Aerosol in a Wet Electrostatic Precipitator. YIFAN WANG, Chenghang Zheng, Xuefeng Zhang, Zhengda Yang, Yi Wang, Dawei Duan, Xiang Gao, *Zhejiang University*

The emission standard have become increasingly stringent in recent years as more attention has been given to the sulfuric acid aerosols. Wet electrostatic precipitator (WESP) is typically used to remove sulfuric acid aerosols. However, removing sulfuric acid aerosols with small size and high concentration were less efficient.

Enhancing the electric field intensity and optimizing distribution characteristics of the electric field are the key to improve the collection efficiency of the WESP. However, the current researches mainly focused on the influence of discharge electrode geometry on V-I characteristic. Few researches have been done on the detail current density distribution which comprehensibly reflects electric field.

In this study, detailed current density distribution on the collecting plate were researched. An experimental WESP which the current density of measuring point can be obtained automatically was designed. Twenty-three kinds of discharge electrodes with different needle shape, length, and spacing were used as the experimental discharge electrode. Firstly, V-I characteristic of the experimental discharge electrode were measured. Then, we investigated the circumferential and axial current density distribution using current measuring device. And fractional discharge electrode were tested in sulfuric acid aerosols.

The results show that the effect of sulfuric acid aerosols space charge is significant and causes corona current decrease sharply at high concentration. Reducing the current density at the entrance by 87% in 53.6 mg/m^3 sulfuric acid aerosols. Increasing the needle length and decreasing the spacing of needles can provide higher corona current density. Interestingly, the rotating of discharge electrode almost makes no differences to the V-I characteristic, but the current density distribution changes significantly. The current distribution becomes more uniform and improves the removal performance. Rotating 30° relative to the vertical surface is the best choice under the experiment condition. And we will develop a numerical modeling to verify the effects for the corona current and collection efficiency in barbed electrode.

5CM.5

Exploring the Methods of Enhancing the Particle Charge in ESP. DAWEI DUAN, Chenghang Zheng, Qianyun Chang, Zhengda Yang, Yi Wang, Yifan Wang, Xiang Gao, *Zhejiang University*

Electrostatic precipitator (ESP) is a widely used particle control device for its high efficiency and wide adaptability. The overall mass based collection efficiencies for ESPs exceed 99%. However, results of field measurements have shown that there is a “penetration window” in the submicrometer size ranges, where the collection efficiency is as low as 70～80%.Hence, improving the collection efficiency on the particle of submicrometer size ranges is the key to decrease the emission concentration of ESP. The key to improve the collection efficiency of the particle of submicrometer size ranges is to increase its charge.

Many factors such as ion density, electrical field strength, particle properties, flue gas parameters and so on can affect the particle charge. The current researches mainly focused on the influence of ion density and electrical field strength on particle charging. Few researches have been done on the influence of particle parameters and temperature on the charge of particles. In this study, an experimental ESP was designed to explore the effects of particle properties (particle size, composition, etc.), flue gas parameters and water droplet humidification on particle charge. The temperature can be controlled from 298K to 383K and water droplet concentration can be controlled from 2.0 to 8.8g/m^3. Six kinds of fly ash with different dielectric constant were used as the experimental particle. An electrical low pressure impactor (ELPI$^+$) was used to measure the fractional particle charge.

The results showed that the particle charge increased with the increasing temperature. The charge of particle with the diameter of 1.2μm was enhanced by 25% with the temperature improved from 300K to 363K. In addition, particle charge increased as the dielectric constant increased. Besides, when the particle had a water layer on its surface, the particle charge was much larger than without the water layer. The average charge of particles larger than 0.5 μm was increased by more than 35% with the water droplet concentration of 8.8g/m^3.

5CM.6

Development of Electrodynamic Dust Shield Technology for Solar Energy Applications. BING GUO, Wasim Javed, Benjamin Figgis, *Texas A&M University at Qatar*

In the Middle East and North Africa (MENA) region, efforts of utilizing the abundant supply of solar energy can be significantly hampered by soiling of solar panels or mirrors due to dust accumulation. Electrodynamic dust shield (EDS) is a technology using electrodynamic activation to repel dust particles accumulated on a surface, which has been proposed for mitigation of soiling. In the past two years, we have carried out laboratory experiments and field tests to investigate the feasibility of this technology. In laboratory studies, we have found the dust removal efficiency to be dependent on dust loading, dielectric cover thickness and other factors. The dust removal efficiency may decrease to very low levels when the dust loading is low, or when the EDS is run in the cyclic-operation mode. Our field tests, run in the cyclic-operation mode, have shown that EDS prototypes can maintain a dust removal efficiency of approximately 14%, which in theory could still result in significant soiling mitigation benefits. Our field test of EDS-integrated solar photovoltaic (PV) modules has recently begun, and produced some very interesting results. In this presentation, we will give an overview of these results and discuss research needs in the very near future.

5CM.7

Electro-scavenging of Airborne Particles by Electro Hydrodynamic Atomizer (EHDA) Generated Charged Droplets.

Arshad Khan, Sanjay Singh, B.K. Sapra, Y.S. MAYYA, *Bhabha Atomic Research Centre, Mumbai*

Airborne particulates generated during various processes in conventional or nuclear industries are controlled /removed by filtration systems based on their particle size using cyclone, fabric filters and electrostatic precipitator. Cyclone is useful mainly for particles of few micrometers and above. High Efficiency Particulate Air (HEPA) is also suitable and have an efficiency of 99.97 % for particle of 0.3 µm but they are not very cost effective as they need to be replaced frequently due to dust loading. Electrostatic Precipitator (ESP) on the other hand, is used for fine particles of less than 0.3 µm. Though, electrostatic precipitators do not require filter replacement, they produce ozone as a by-product and collection efficiency is low for size 0.1 – 1.0 µm [1].

Alternatively, electro-scavenging of aerosols using charged particles is an upcoming technology in the area of air cleaning. Its advantage is that it does not give rise to ozone in the ambient environment and does not add to the noise level. Herein, we studied the depletion of lab generated aerosols with EHDA generated high charge (~10^4 elementary charges) droplets and its potential for utilization in air cleaning applications [2].

An EHDA based air cleaning system is designed [3] & fabricated and aerosol scavenging characteristics are studied using smoke and nebulizer generated NaCl aerosols. Both types of aerosols were fully characterised with respect to their number, size and charge distribution. For smoke aerosol, size dependent aerosol collection efficiency showed minima of 20% for particle diameter of 30 nm; increasing to as high as 90% for particle diameter greater than 100 nm. For NaCl aerosols, collection efficiency is almost flat with respect to particle size. The variation is 70% to 90% for the particles more than 200 nm.

The EHDA based cleaning system showed good particle removal efficiency, however a question arises as to whether the removal occurs because of electro-migration of aerosols in the capillary electric field of EHDA or due to scavenging of aerosols by droplets. To confirm this, a comparative aerosol removal study was carried out at applied capillary potentials of 0 V and 4 kV (which is just below the operating voltage of EHDA) and with operating EHDA. The experiment confirms the aerosol removal by interaction of charged droplet with aerosol particles. Results from the current system have been very encouraging for its utilization in air cleaning application.

High-efficiency Particulate Removal by Photoionization Enhanced Electrostatic Precipitation. TANDEEP CHADHA, Jiaxi Fang, Pratim Biswas, *Applied Particle Technology, LLC*

Over the past several years, indoor air quality has become a matter of increasing concern both due to the presence of non-viable pollutants (particles, volatile organic compounds, and gaseous pollutants) and viable pollutants (bacteria, viruses and mold). The efficiency of current media-based filters is limited to particulate removal and is proportional to the pressure drop across the filter. Electrostatic precipitators (ESPs) are considered a viable alternative to media based filtration technology since they contribute a much lower pressure drop and do not require frequent filter replacement. However, ESPs have a limited removal efficiency especially for ultrafine particulates and are associated with the production of harmful byproducts such as ozone.

In this work, we present the development of a scalable photoionization enhanced electrostatic purification (PE-ESP) technology for high efficiency removal of particulates [1]. A model driven approach was used to design and develop a parallel plate PE-ESP system. Air jet atomization of a KCl solution was used to generate aerosolized particles and the filtration efficiency of the SXC-ESP unit was measured using an optical particle counter (OPC) and a condensation particle counter (CPC).The PE-ESP system shows a 97-99% particulate removal efficiency in the 0.2 to 1 µm size range without the production of any measurable ozone. The efficiency without the photoionization was 50-60% in the same size range. The efficiency predictions from the model match well with the experimental measurements for both a conventional ESP as well as the PE-ESP. Owing to its high efficiency and negligible ozone production, the PE-ESP system has the potential of being used as a replacement for media based filters.

5IM.1

Scattering Matrices of Single Levitated Particles. ALEXANDRIA JOHNSON, Maria Zawadowicz, Sara Lance, Daniel Cziczo, *MIT*

Suspended particulates are a ubiquitous feature of planetary atmospheres. However, major gaps remain in our understanding of how non-spherical particles scatter and polarize incident radiation. Modeling the highly complex scattering phase functions produced by non-spherical particles is challenging and broad stroke simplification of particulate properties, such as with an oblate spheroid approximation, can lead to large uncertainties in numerical model outputs and satellite retrieval corrections.

With this in mind we aim to directly measure how non-spherical atmospheric particulates interact with radiation through the development of a single particle scatterometer. Our novel instrument consists of a vapor diffusion electrodynamic balance (EDB), used to levitate single particles in a precisely controlled atmospheric environment, coupled with a photomultiplier for the collection of a scattering phase function, or scattered light as a function of angle along the plane of illumination.

Here we will discuss the development of our EDB scatterometer, validation experiments with spherical particles, and preliminary results on non-spherical particles. For spherical validation experiments our results will be compared directly to Mie theory and used to address any biases in our measurements. Although single particle studies allow for the precise control of a sample and its environment, their relevance to atmospheres and the complexity therein can be questioned. To address this we will discuss the relationship between single particle and bulk sample (or particle ensemble) non-spherical scattering phase functions through comparison with data from the Amsterdam-Granada Light Scattering Database.

Future work will be done towards expanding the system to include the collection of polarized light, with the ultimate goal of retrieving Muller matrix elements for a full description of scattering on the single particle basis. We also aim to expand the temperature regime of the EDB beyond that of Earth for atmospheric studies relevant to other solar system bodies and ‘cooler’ exoplanets.

5IM.2

Dual-Beam Optical Tweezers Development for Measuring the Dynamic Evolution of Aerosol Surface Tension and Viscosity. Aidan Rafferty, KYLE GORKOWSKI, Thomas Preston, *McGill University*

Understanding the evolution of glassy particles in the atmosphere has important implications when modeling mixtures of inorganic and organic particles. A glassy state of organic particles affects the particle to gas phase partitioning of organic species, diffusion of oxidants into the particle and the phase state of clouds, as they can serve as heterogeneous ice nucleating particles. To better understand how glassy states, evolve in the atmosphere as humidity and aerosol composition changes we have built a dual-beam optical tweezers (D-BOT).

The D-BOT system has two optical potential wells which trap a single droplet in-between them. The optical potential wells balance each other, pulling equally on opposite sides of the droplet. By increasing the laser power in the traps, the optical force pulling on opposite sides of the droplet causes it to deform into an ellipse. The surface tension of the droplet balances the optical force resulting in the elliptical deformation. We use the equilibrium deformation at high laser power to measure the surface tension of the droplet. Then after a viscous system has been deformed to an ellipse, the droplet viscosity is measured from the relaxation back to a sphere when the laser power is lowered. The physical dimensions of the ellipse and effective refractive index are retrieved from a newly developed fitting program for the measured elliptical whispering gallery modes (WGMs). The differences between the optical pathlengths for the major and minor axis of the ellipse result in shifts in the WGMs. These shifts in the WGMs are used to retrieve the ellipse deformation in the major and minor axis. We will present the new WGM analysis method for elliptical WGMs and with it, we will present results on surface tension and viscosity measurements for simple chemical systems.

Anatomy of Single Airborne Aerosol Particle Using Laser-trapped Submicron Position-resolved Temporal Raman Spectra. Aimable Kalume, Chuji Wang, Joshua Santarpia, YONG-LE PAN, *U.S. Army Research Laboratory, Adelphi, MD*

The study of various molecules located in different positions within a micro-sized particle in its natural phase is essential to a deeper understanding the functions of these molecules, such as the reaction of DNA, RNA, and protein molecules within a cell in buffer solution or different molecules within an airborne aerosol particle freely suspended in the atmosphere as they respond to various environments. Here, we present a new method that can measure the time-resolved Raman spectra from multiple sections across a laser-trapped single airborne particle to capture these crucial functions. Submicron resolved (up to 200 nm × 200 nm) temporal Raman spectra from different positions in a laser trapped particle can be obtained. Droplets in super micron size composed of diethyl phthalate (DEPh), glycerol, or their mixture have been used to test the new method. The results directly demonstrated the micro-cavity enhanced effects within a droplet, also the morphology, dynamics of phase-separation and evaporation of the mixed droplet. By inspecting the physical structure of the mixed droplet, we learned that the two liquids quickly separated and formed a core-shell-like morphology, in which the glycerol was mostly concentrated in the core, and the DEPh dominated around the outer layer of the droplet, as the mixed liquid was aerosolized. We also found that DEPh emerged to the surface and evaporated more quickly, then the glycerol evaporated slowly, but both chemicals in their mixed droplet evaporated much faster than that in their own pure droplet forms. This method should supply a powerful tool for monitoring various chemical reactions and understanding molecular functions at different locations within a single cell, spore, or particle in life and atmospheric science.

5IM.4

Design and Application of Aerosol Optical Tweezers to Explore Temperature Effects on Phase Separation and Acidity of Organic Aerosol at Subzero Temperatures. HALLIE BOYER, Kyle Gorkowski, Neil Donahue, Ryan Sullivan, *Carnegie Mellon University*

Phase and morphology in atmospheric aerosols are critical for understanding gas-particle and particle-cloud interactions, yet they remain hard to measure and predict due to multiple operative processes and properties. Further, there is currently a lack of data needed to train predictive models for explicit temperature dependence, especially data obtained from direct measurements on particles rather than bulk solutions. Phase separation is governed by ambient conditions and particle properties that are difficult to measure in situ, such as particle composition, interfacial tensions, and pH; thus, predictions frequently rely on a bulk perspective. Liquid-liquid phase separation can result in a core-shell or partially-engulfed morphology, where the aqueous phase is the core of the particle and the organic phase is present either as a complete shell or included lens, respectively. In the atmosphere, the morphology of the particle and the presence of an organic surficial layer can profoundly affect the particle's ability to scatter light and interact with chemical vapors and water. We directly determined pH, surface tension, and morphology of optically levitated particles using cavity enhanced Raman spectroscopy while monitoring changes in ambient conditions, including chemical composition and temperatures ranging from -20 to 40 C.

We use an aerosol optical tweezers (AOT) platform with a new chamber design for the integration and real-time measurement of particle properties under relative humidity and temperature control. Previously, we determined particle morphology of secondary organic aerosol in the AOT and identified core-shell and homogenous morphologies in response to organic vapor condensation and relative humidity. In the new chamber, we have explored the effects of pH and surface tension on phase mixing of multicomponent aerosol particles and investigated sub-zero temperatures of each property. The AOT provides steerable, contactless traps for single droplets of ~5 micron radii. Particles trapped in the AOT can reach metastable states, such as sub-cooled liquid states or supersaturation of solute with respect to solvent or other solute species, enabling measurements where data are scarce due to inaccessibility in bulk experiments. We determine surface tension by analysis of elastic backscattered light induced by the coalescence of two droplets trapped in a holographic optical trap. Surface tensions are necessary for predictions of particle morphology using spreading coefficient analysis, to predict aerosol interfacial composition, as well as for determination of cloud activation through Köhler theory. Finally, measurements of surface tensions as a function of temperature are applied to an analytic surface thermodynamic model to produce accurate predictions of interfacial tensions where little or no experimental data are available.

In-Situ Characterization of Aerosol Nanoparticles at Close-To-Ambient Conditions by Small Angle X-Ray Scattering (SAXS).

PAULUS S. BAUER, Heinz Amenitsch, Bernhard Baumgartner, Christian Rentenberger, Paul M. Winkler,
Universitaet Wien & VDSP, Vienna, Austria

The characterization of airborne particles is one of the main tasks in aerosol science. Especially the analysis of nanoparticles below 100nm requires particular attention, since they exhibit highly dynamic behavior that may impact cloud properties and hence global climate (IPCC, 2013). To determine the size and number concentration of aerosol nanoparticles Differential Mobility Particle Sizer (DMPS) and Condensation Particle Counter (CPC) are mostly used. A common drawback of these techniques is that they remove the aerosol particles from their original environment. Thereby, nanoparticles can get modified (e.g. by evaporation) or get lost (e.g. by wall collisions inside the instrument), which may affect the measured size distribution and concentration (Wang, J. et al. (2002). J. Aerosol Sci. 33, 6, 843).

An in-situ measurement technique can overcome these shortcomings of the conventional aerosol instruments. Small-angle X-ray scattering (SAXS), commonly used in material science or in biochemical process analysis, can fill this gap. It is capable of measuring in-situ particle size distribution in the nanometer range (Sztucki, M. et al. (2007), J. Appl. Phys. 101, 114304. Laksmono, H. et al. (2011), Phys. Chem. Chem. Phys. 13, 5855). These studies were operated with extremely high nanoparticle concentrations of ~10^{12}/cc and carrier gas pressures ~2 kPa to acquire proper SAXS signals. Conventional aerosol instrumentation on the other hand typically requires measurement conditions close to ambient pressure and concentrations not exceeding 10^{6}/cc.

Here we report synchrotron-based SAXS experiments on nanoparticle characterization. To provide a representative environment for aerosols a flow tube was operated at ambient pressure and concentrations of about 10^{6}/cc. This leads to a very low volume fraction of about 10^{-10} (see Beaucage, G. et al. (2004), Nat. Mater. 3, 370). A critical aspect for SAXS experiments with aerosols and this low volume fraction is the background scattering signal originating from the carrier gas. The air background usually is of the same order of magnitude as the signal from the nanoparticles. This issue was lately resolved by replacing air with helium as carrier gas. The usage of helium provides the opportunity of operating the flow tube under ambient conditions (temperature, pressure), and permits the parallel sampling by modified state-of-the-art aerosol instruments like CPC and DMPS system. To complete the picture, electron microscopy images were taken from aerosol samples.

Aerosol Spark Emission Spectrometer (ASES) for the Measurement of Trace Metals Concentration in Particulate Emissions from the Combustion of Coal in a Household Heating and Cooking Stove. NATHAN REED, Yixiang Zhang, Zhichao Li, Sameer Patel, Jiayu Li, Zehua Wang, Lina Zheng, Pramod Kulkarni, Pratim Biswas, *Washington University in St. Louis*

A recent study by the World Health Organization found that 92 % of the world's population lives in regions with unsafe ambient air quality. This situation challenges us to identify the source of pollutants, investigate their properties, and understand how they affect health and the environment. Investigating the properties of pollutants, especially particulate matter (PM), is critical for understanding both their source and subsequent effects. Based on its chemical composition and physical characteristics, PM can be attributed to sources such as coal powerplants, vehicle emissions, or biomass combustion. Although the mass concentrations of PM (PM1, PM2.5, and PM10) are almost exclusively used to regulate air quality, other physical metrics, such as number concentration, surface area, and even chemical composition might be a better way to represent the health effects of PM [1].

The accessibility and affordability of instruments critically hinder the comprehensive characterization of PM. Low-cost and compact instruments are being developed to measure the characteristics of PM in real time. These measurements currently are limited to the aerosol physical properties such as mass concentration and size distribution [2, 3]. Low-cost portable instruments to capture organic and inorganic species have not yet been developed thus these measurements are usually done by collecting filter samples for off-line analysis. Instruments that could perform chemical analysis in situ would reduce sampling costs, logistical problems, and measurement artifacts from storage and transportation of filter samples.

This work focuses on a portable instrument, the aerosol spark emission spectrometer (ASES) for quantitative characterization of the elemental content of PM. This instrument employs atomic emission spectroscopy using spark microplasma as the excitation source [4, 5]. PM is collected on the tip of a cathode in a coaxial electrode system via a one-step charge-and-collect scheme using corona discharge [6]. The collected sample is then ablated and excited by the spark microplasma, and the resulting atomic emission is recorded by a broadband CCD spectrometer for elemental identification and quantification. The utility of the ASES is demonstrated in this study by applying it to measure elements present in PM emitted from a solid-fuel cooking and heating stove. These stoves are one of the biggest contributors of PM emissions in countries such as India and China. In addition to real-time measurements from the ASES, filter samples were collected and analyzed using an ICP-MS to assess the accuracy of the real-time performance. In addition to measuring the elemental composition, we also used various real-time instruments to track the different phases of the burn-cycle in the stove, and to correlate physical PM metrics and elemental composition measurements.

Measuring Functional Group Composition in Complex Environmental Samples: Infrared Photodissociation of Ions from Secondary Organic Aerosol. Emma Walhout, Jonathan Martens, Giel Berden, Jos Oomens, Jesse Kroll, RACHEL O'BRIEN, *College of William and Mary*

Secondary organic aerosols (SOA) are a large fraction of the organic particulate matter in the atmosphere with impacts on climate, air quality, and human health. The effect of aerosols on the climate is one of the largest uncertainties in estimates of radiative forcing. Much of this uncertainty is driven by the complexity of the organic fraction, with thousands of different molecules in an aerosol population. Mass spectrometry can be used to analyze the molecular composition of organic aerosols, however, information on the chemical structure and functional groups is typically lost with this type of analysis. By combining information on the functional groups and the molecular formulas in an aerosol sample, we can work towards identification of individual molecules in the mixtures. Infrared multi-photon dissociation (IRMPD) uses IR radiation to fragment ions in a mass spectrometer. With a tunable free electron laser as the light source, an action spectrum for ions can be generated in the fingerprint IR region (~600-1900 cm-1). These spectra, in combination with the fragment ions (MS/MS type fragments), provide details on the chemical structures of the ions. In this work we present the first application of IRMPD analysis, using the FELIX tunable free electron laser, to characterize compounds in SOA produced via ozonolysis of a-pinene.

5IM.8

Bounding Uncertainty in Functional Group Reconstruction of Organic Carbon and Organic Matter Concentrations in PM2.5 For the Improve Monitoring Network. MATTEO REGGENTE, Ann Dillner, Satoshi Takahama, *EPFL*

Functional group analysis by Fourier Transform Infrared (FT-IR) spectroscopy provides a chemically informative representation of the organic matter (OM) mass in aerosols. The molecular mixture conceptualized as a collection of functionalized carbon atoms can be used to estimate organic carbon (OC) content, degree of oxygenation, oxidation state, and organic matter to organic carbon mass (OM/OC) ratios for a large portion of the aerosol organic fraction (Takahama and Ruggeri, 2017). In previous work, this technique has been used to provide complementary information to mass spectrometry measurements which provide molecular speciation for a small fraction of the mass, or mass fragment composition commonly used for OM characterization (e.g., Faber 2017).

Functional group calibrations are typically prepared in the laboratory using simple mixtures and extrapolated to ambient aerosol spectra which contain a diverse set of compounds. While the potential of FTIR for quantitative aerosol research using this approach has been studied in separate contexts, a thorough investigation into the consistency of functional group estimation has not yet been conducted. In this work, we systematically explore the influence of spectral processing (e.g., baseline correction), selection of laboratory standards, and calibration algorithms on predictions of functional group distributions. Using 250 laboratory standards and 794 ambient sample spectra from 7 urban and rural sites in the IMPROVE monitoring network, we present the range of predictions that are possible under different assumptions. We also compare the physically-based peak-parameter representation for building calibration models to statistically-based multivariate regression models and their contrasting strengths, particularly for constraining the carbonyl apportionment to carboxyl and other non-acid functional groups. We also identify samples with higher loadings of larger particles from mineral dust and other sources that lead to excessive scattering and the Christiansen peak effect, which affect the quality of predictions. Directions for future research resulting from this analysis are presented.

Spark Production of Internally Mixed Nanoparticles by Oscillating Sparks. Jicheng Feng, Nabil Ramlawi, George Biskos, ANDREAS SCHMIDT-OTT, *TU Delft*

We show that spark synthesis of mixed NPs allows a virtually unlimited number of combinations. Oscillating sparks are produced, in which cathode and anode are periodically exchanged with a frequency of around 10 MHz during a discharge time in the order of 1 µs. Nanoparticulate alloys of materials immiscible in the bulk can be produced this way. We show that the mean composition can be tuned through the spark characteristics and that a model predicts the broadness of the distribution.

5MS.2

Scaling-up of Extractor-Free Electrohydrodynamic Emitter Arrays in Linear Configuration. Nikolas Sochorakis, Jordi Grifoll, JOAN ROSELL-LLOMPART, *Universitat Rovira i Virgili*

Simultaneous operation of multiple electrospray emitters (multiplexing) have been used in virtually every known application of electrospray, to achieve relevant production rates: Pharmaceutical particle synthesis, surface coating, micro-electronics cooling, mass spectrometry in nanoelectrospray mode, microprotein arrays, 3D printing, microcombustion, and colloidal propulsion of spacecraft. Most often, electrospray emitters are arranged either in square or hexagonal 2D patterns, or in a straight line, as in the present study. When the concentration of the emitters is raised, the electrostatic interactions between the Taylor cones result in non-uniform electrical field, which can interfere with the spraying. Therefore, an important aim in this field is the development of configurations which allow robust, stable spraying.

Often, to achieve this goal, the electrospray emitters are positioned very near the counter electrode. In this way, the Taylor cones are shielded from one another and from the spray charges. When such counter electrode is a conducting ring or perforated plate, in order to extract the generated aerosol, this electrode is called 'extractor'. Since operating configurations with extractor electrodes can become challenging, at the beginning of this research we had reasoned that they would not be required in 1D arrays. Therefore, we have developed and evaluated extractor-free linear designs. In them, the counter electrode is much farther from the Taylor cones than the inter-cone spacing (or pitch) (about 4 times or more), and 'blind emitter' electrodes are placed at the ends of the array. At the same time, a backplate electrode is positioned behind the emitters, set at the same electrical potential.

We have characterized the conditions leading to stable cone-jet mode and spray plume behaviour as a function of the geometrical parameters of the arrays and the relevant liquid properties (e.g. electrical conductivity). We find that:

(1) It is possible to produce stable spraying along the entire linear array without the aid of extractor-type electrodes, over wide ranges of the applied voltage, using two blind emitter electrodes are located at either end of the array;

(2) The electrical potential difference needed to sustain stable spraying increases with the number of spraying emitters in the array, yet tends towards an asymptotic value, thus becoming finite regardless of array length;

(3) In long arrays, there are three distinct regions: an 'inner' central region, in which the sprays shapes are similar, unaffected by the length of the array; and two 'outer' regions, located at the ends of the array, where 'end effects' are concentrated, in which the sprays become broader.

(4) At high electric field strength, the spray symmetry breaks, as the Taylor cones retract towards the emitter tube (upstream) while they misalign, similarly as found for electrospying from single emitters, except in the linear array the direction of the emission is "seeded" by errors in the emitters' positions.

5MS.3

Magnetic Nanoparticle Chain Formation in a Combined Electric and Magnetic Field. CALLE PREGER, Knut Deppert, Maria E Messing, *Lund University*

Magnetic nanoparticles have been widely studied due to its many interesting properties and for their potential use as magnetic memory device and in medical diagnostic. Aerosol technologies provides a good mean to produce magnetic nanoparticles and the spark discharge generation of engineered nanoparticles enables formation of complex alloys with controlled size and concentration in a broad size range without agglomeration. The nanoparticles are typically deposited onto a substrate by using an electrostatic precipitator (ESP) and as the concentration of particles on the substrate increases random clusters are formed.

In this study, magnetic nanoparticles have been generated by spark discharge and the clusters formation on the substrate has been studied after the nanoparticles have been exposed to a magnetic field. We will show that it is possible to assemble individual nanoparticles into chains of magnetic nanoparticles in the presence of a magnetic field. The sparsely spaced nanoparticles are exposed to a magnetic field in the aerosol flow, the particles attract and collide and form chains of particles enabling formation of structures not possible with an electrostatic precipitator (ESP) alone. We will show the combined effect on magnetic nanoparticles from a magnetic field prior to deposition and from an electric field at deposition. This enables standing chains of nanoparticles and in some cases arcs of nanoparticles. By varying the strength of the magnetic field, the time the particles are exposed to the magnetic field, the concentration of particles in the gas flow and the size of the particles differently sized chains and shapes are formed and deposited on the substrate.

5MS.4

3D Nano-Printing via Electric-Field Assisted Aerosol Lithography. WOOIK JUNG, Yoon-ho Jung, Mansoo Choi, *Seoul National University*

Ion assisted aerosol lithography (IAAL) is an aerosol-based 3 dimensional (3D) assembly technique, which utilizes electrostatic focusing effects to manipulate the trajectory of incoming charged nanoparticles. (Kim et al., 2006; Lee et al., 2010; Choi et al., 2015.) Charged aerosols can be directed into openings in photoresist patterns or apertures in masks, making it possible to produce 3D nanoparticle structures whose shapes are defined by the cross-section of the openings in the photoresist layer or the mask.

Building upon this, here we show that translating the mask during the nanoparticle deposition process holds promises to be a novel 3D nano-printing technique. The shapes of the 3D nanoparticle structures are now determined not only by the cross-section of the mask openings, but also by the mask trajectory. Interestingly, we found that varying the horizontal mask translation speed leads to two distinct process regimes: ‘3D growth’ mode at slower translation speeds and ‘3D writing’ mode at faster translation speeds.

In ‘3D printing’ mode, high aspect ratio nanowires can be assembled by vertical upward translation of the mask during particle deposition. In principle, the process can continue indefinitely by matching the mask translation speed to the vertical growth rate of the structures. Adding horizontal components in the mask motion allows for creation of structures with various 3D shapes, such as slanted pillars or helices. In ‘3D writing’ mode, faster horizontal translation of the mask causes the particles to land next to the existing clusters rather than being deposited on them. This enables particle assembly whereby the structures do not lift off vertically from the substrate. Multiple sweeps of a given trajectory while depositing particles allow the clusters to grow in thickness and become ‘walls’.

In addition to the presented capability of directly printing 3D shapes using this technique, the ability to switch the aerosol material on demand with relative ease contributes to the expected versatility of this process, and further development and fine tuning will benefit applications that require multi-material 3D nanostructures.

This work was supported by Global Frontier R&D Program on Center for Multiscale Energy System by National Research Foundation (NRF) under the Ministry of Science, ICT and Future Planning, Korea (Grant no.2012M3A6A7054855).

Low Temperature Plasma Synthesis of Pure and Uniform III-V Semiconductor Nanoparticles from Bulk Metals. NECIP BERKER UNER, Elijah Thimsen, *Washington University in St. Louis*

III-V semiconductors constitute a major component of optoelectronic materials. Although the synthesis of many of the III-V materials in nanoparticle form, for example GaAs, InP and InSb, has been well developed, stibnide and nitride particles still do not have an established general route of synthesis. The difficulties in the synthesis of these materials stem from the unavailability of chemically pure precursors or the extremely toxic nature of their chemical precursors, and the very high melting point of nitrides. In this work, aerosols generated from evaporation and condensation of pure bulk metals are utilized as precursors. These aerosols were mixed and then sent into a low temperature plasma (LTP) of argon. It has been recently shown that metal particles vaporize in the LTP despite the low gas temperature, and the generated vapor leads to the formation of monodisperse particles via a process involving nucleation and condensation [1]. Accordingly, the LTP was used to form the III-V compound nanoparticles by vaporization of the feed aerosols, followed by nucleation and condensation. Coagulation is largely prevented due to unipolar negative charging. The process yields nanoparticles which are monodispersed, spherical, crystalline and stoichiometric. This study focuses on the synthesis of Ga-based III-V semiconductor nanoparticles, and results on the synthesis of GaSb and GaN will be reported. Aerosols of pure Ga and pure Sb, and gaseous nitrogen bearing species were used as the precursors. Extensive ex-situ characterization of the produced materials by high resolution transmission electron microscopy, energy dispersive x-ray spectroscopy, electron-energy-loss spectroscopy, x-ray diffraction and inductively-coupled plasma optical emission spectroscopy will be presented. Operation of the aerosol sources will also be discussed.

Easy On-demand Aerosol Doping Process to Fabricate Safer Antimicrobial Telluride Nanocomposites. DAE HOON PARK, Milan Gautam, Sung Jae Park, Jungho Hwang, Jong Oh Kim, Jeong Hoon Byeon, *Yonsei University, Korea*

On-demand synthesis of telluride nanostructure was developed from single-pass aerosol-based process under ambient gas flow conditions. Te nanoparticles(NPs) were assembled with Ag or Cu NPs using 4-Rod spark ablation system. Te NPs were partially alloyed with Ag or Cu NPs, resulting in 6 different formations of telluride nanocomposite. Then, their antimicrobial abilities were evaluated and compared with Ag, Cu and Te NPs. The minimal inhibitory concentration (MIC) values of the telluride nanocomposite against both Gram-positive bacteria (S.epidermidis) and Gram-negative bacteria (E.coli) were comparable to which of Ag or Cu NPs (that are famous as the antimicrobial agents) and their in vitro cytotoxicity was lower than which of Ag or Cu NPs as well. The simple on-demand doping process proposes a novel platform to constantly fabricate nanostructures which have safer antimicrobial activity without significant cytotoxic effects and environmentally friendly process.

Plasma Synthesis of Mass-Produced CNT Materials. BRIAN GRAVES, Jean de La Verpilliere, Simon Engelke, Fiona Smail, Michael De Volder, Adam M Boies, *University of Cambridge*

The exceptional mechanical, thermal, and electrical performance of carbon nanotubes (CNTs) makes them ideal for a wide range of applications, however they are costly to produce and difficult to integrate effectively with other materials. We have developed a microwave plasma based process that can continuously synthesize several novel gas-phase CNT materials.

The presentation will demonstrate how transition metal catalyst particles are nucleated from the plasma and CNTs are grown from these particles in a furnace via gas-phase CVD. With this approach, a CNT-metal oxide hybrid material has been produced for use in lithium ion battery anodes. Findings from battery cycling demonstrate how this material offers increased storage capacity, greater cyclability, and a higher resistance to degradation from high discharge powers. Additionally, it is also possible to produce CNTs for structural and thermal applications. If the CNTs can achieve a sufficient length and number concentration they coagulate to form an aerogel which can be extracted continuously from the reactor. The self-assembled CNT structure can be wound to form fibres and mats which can be easily integrated into composites, wires, and heat pipes, among many other applications.

This plasma-based process exhibits several key advantages over other techniques. The extremely high temperature of the plasma permits vaporization of a wide range of precursor materials, including those in powdered, elemental form which are ideal for an industrial process since they are cheap and readily available. The plasma also has a high energy density, meaning that a large material throughput can be achieved with a small system. Large-scale production of these materials with this method could contribute to significant advances in materials for an array of engineering fields.

Nanographene Aerosol Production from Natural Gas by Microwave Plasma. RANDY VANDER WAL, Arupananda Sengupta, Evan Musselman, Kurt Zeller, George Skoptsov, *The Pennsylvania State University*

Graphene is the latest carbon allotrope, revolutionizing carbon science and igniting commercial interests. Synthesis processes are well known, beginning with mechanical exfoliation, varied graphene oxide (GO) routes and chemical vapor deposition (CVD). The former two processes begin with a pristine sp^2 carbon framework, with the GO path requiring its restoration. The CVD approach is by contrast a bottom-up approach in contrast to the former two being top-down approaches. It requires, however, a metal catalyst to activate the hydrocarbon decomposition and/or mediate the sp^2 framework formation. Without this metal an amorphous form of carbon forms, either as pyrolytic deposition if upon a surface or as a form of "soot" if as an aerosol. This presentation highlights aerosol (substrate-free) formation of graphene nanoplatelets in a microwave plasma. Whereas pyrolytic decomposition of hydrocarbons typically produces unstructured carbon, the nanoplatelets are characterized by dimensions of 200 – 500 nm, occurring in stack of 2-6 with morphology resembling mildly crumpled paper. Present selectivity is 50% +/- 20% on a solid carbon basis. Accompanying spectral diagnostics are used to characterize the reacting flow. Possible formation paths will be discussed. The co-production of hydrogen and high-value carbon materials from natural gas offers opportunities to reduce the costs associated with large-scale production of industrial or fuel hydrogen or platform chemicals while also producing synthetic, high-value carbon products such as the graphene nanoplatelets. H Quest Vanguard Inc. is developing microwave plasma processing of natural gas as a modular, compact and portable technology for production of hydrogen and premium carbon products.

Urban Substrates: Atmospheric Particle-bound Radionuclide Traps - The Example of Beryllium-7. PHILIPPE LAGUIONIE, Denis Maro, Luc Solier, Marianne Rozet, Didier Hébert, Pierre Roupsard, Olivier Connan, *IRSN*

In the context of chronic or accidental release of radioactive particles into the atmosphere, knowing atmospheric particle-bound radionuclide total (dry and wet) deposition flux on ground surfaces and the deposited radionuclide mobility is essential to assess risks both on populations and environment. Fluxes of deposition, of re-emission into the atmosphere, and of radionuclide transfer between rainwater and ground surfaces differ in urban and rural environments which are characterized by different surface types, heterogeneities and local micro-meteorologies. In particular, interactions between rainwater and urban surfaces have often been only considered as dry-weather deposited particles washing by rainwater flowing. First, this study investigated the ability of seven urban substrates (horizontal asphalt and grass, vertical façade coating and glass, and tilted zinc, slate and tiles) to permanently trap rainwater beryllium-7 at month scale. Beryllium-7 is a radioactive tracer naturally present in the environment (^{7}Be, $T_{1/2}$=50.3 days). Second, results were extended to a urban catchment (Pin Sec urban catchment in Nantes; area of 310 000 m²), knowing the repartition of each surface type in the total area of the catchment. The experimental set-up consists of two sets of each substrate: the first one was exposed to wet and dry atmospheric particle-bound ^{7}Be deposition whereas the second one was only exposed to dry deposition. The results showed that mean urban substrate retention rates present disparities linked to the surface orientation (main factor) and the substrate nature (secondary factor). Retention rates of horizontal, tilted and vertical surfaces were respectively between 65% and 93%, 48% and 59%, and 3% and 4%. The results also showed that the Pin Sec urban catchment area could trapped between 57 ± 25% and 83 ± 33% of the rainwater ^{7}Be at month scale.

5RA.3

Particle Emissions from Brakes – Sampling, Quantification and Characterization. MICHAEL ARNDT, Athanasios Mamakos, Klaus Augsburg, David Hesse, Fekix Wenzel, *AVL List GmbH*

With the exhaust of modern engines being cleaned up efficiently by aftertreatment systems, non-exhaust sources of particles (brake and tire wear) contribute significantly to the total amount of particulate matter emitted by today's vehicles. While tire wear emissions are difficult to quantify as they also depend strongly on the type of pavement, brake dust can be measured under laboratory conditions on a brake dyno. Researchers working on brake emissions employ a wide range of sampling and measuring techniques. The size spectrum of particles emitted by brakes is much broader than for combustion emissions. This results in specific requirements for the design of the sampling system.

In a dedicated measurement campaign on a specifically designed dilution tunnel installed in a brake dyno, different types of brake pads have been tested under various test cycles (WLTC, AK-Master) and specific baking manoeuvres simulating specific driving conditions.

It could be seen that moderate and more aggressive braking manoeuvres result in substantially different particle emissions (particle number, size distribution and PM mass).

Different instrument techniques have been used to quantify the particle emissions. Both thermally treated and untreated samples were sampled for particle number counting using CPCs with different cut-off sizes. Light absorption in the near infrared (i.e. by black carbon) has been quantified by using an AVL Micro Soot Sensor. Multiple PM filter samples have been collected by an AVL PM-PEMS to determine total PM emissions and to perform chemical analysis.

5RA.4

On-road Measurements of Secondary Aerosol and Size Dependent Number Emission Factors for Motorway Traffic Emissions across Europe Using a Mobile Laboratory Setup. MIIKKA DAL MASO, Joni Heikkilä, Miska Olin, Pauli Simonen, Antti Rostedt, Erkka Saukko, Heino Kuuluvainen, Joni Kalliokoski, Outi Potila, Anssi Järvinen, Mikko Poikkimäki, Topi Rönkkö, Jorma Keskinen, *Tampere University of Technology, Tampere, Finland*

Motorways make up a minor fraction of roads in Europe but carry a disproportionately large amount of traffic. Vehicle emission measurements have shown that highway driving at high engine loads may cause above average emissions of both primary and secondary particulate matter. These factors together make highways a significant source of air pollutants. Presently, comprehensive data of simultaneous primary and potential secondary aerosol mass measurements on motorways does not yet exist. We present data from three trans-European measurement expeditions that were carried out on highways reaching from Southern Finland to the Mediterranean, covering in total close to 8'000 km of highways. This dataset elucidates the relative fractions of primary and secondary emissions for highway driving, as well as gives new insights on the particle number emissions for highway driving.

The measurements were performed in 2015 and 2016 aboard the Tampere University of Technology Mobile measurement unit, a van modified to house a mobile laboratory setup, accommodating high-quality aerosol and trace gas observation setups. The modifications include a lithium battery powered inverter power supply with a supplementary charging generator powered by the van engine allowing continuous measurement instrument operation while driving. In addition, the van is fitted with aerosol and gas sampling lines, instrument installation shelving, a GPS and weatherstation, and a temperature regulation system. The sampling inlets were characterized with polydisperse aerosol and found to have good transmission efficiency for particles in the 1-1000 nm size range.

During the trans-European expeditions the instrumentation aboard the measurement unit consisted of aerosol size distribution instrumentation (Dekati ELPI), aerosol number concentration instrumentation (TSI and Airmodus CPC:s), trace gas detectors (CO_2, NO_x, O_3), and a fast-response oxidation flow tube (OFR) for the simulation the conversion of freshly emitted aerosol to photochemically aged aerosol (TUT Secondary Aerosol Reactor, TSAR). To bring the measured concentrations into the instrument's detection range, we used bridge dilution systems.

Measurements were predominantly performed on highways, with the driving speed over 80 km/h. The aerosol number concentrations were found to be clearly elevated in comparison to background. Motorway median number concentrations exceeded $4 \cdot 10^4$ cm^{-3}. On all expeditions, we found a significant fraction of particles in the sub-3nm particle size range, in line with recent findings that traffic is a significant source of nanocluster aerosol. Using CO2 data, we estimated average high-speed motorway driving number emission factors. Measurements using the the TSAR OFR showed that concentrations of potential secondary mass clearly exceeded the primary mass emissions, and our measurements also demonstrate that the high time resolution of the TSAR enables on-road emission factor determination of secondary aerosol.

Phenomenology and Sources of Submicron Aerosol Particles in a Mediterranean Harbour. BENJAMIN CHAZEAU, Grégory Gille, Boualem Mesbah, Brice Temime-Roussel, Henri Wortham, Nicolas Marchand, *Aix-Marseille Université, CNRS, LCE FRE 3416*

Marseille is the second largest city of France and the largest harbour of Mediterranean Sea. It is a challenging environment for air quality, combining an active photochemistry with high ozone concentrations and multiple anthropogenic sources including industrial activities (steel plant, refineries, and various petrochemical industries) and shipping (El Haddad et al. 2011). In order to document, on the long-term, the physico-chemical properties of fine particles, their sources and their evolution from day to multiyear period scales, we implemented an aerosol supersite in an urban background environment: Marseille-5avenues (MRS-5av).

In addition to air quality regulatory indicators (PM2.5, PM10, NOx, O3, SO2), we installed a ToF-ACSM (Time of Flight - Aerosol Chemical Speciation Monitor) for the analysis of the non-refractory fraction of submicron particles (OA, nitrate, amonium, sulfate) an Aethalometer (AE33) for the analysis of black and brown carbon (BC, BrC), an online metals analyser (Xact) and a SMPS (Scanning Mobility Particle Sizer) for the study of the aerosol size distribution (10-1100 nm).

A one-year real-time dataset collected between February 2017 and February 2018 is presented here. ToF-ACSM OA mass spectra were analyzed by means of Positive Matrix Factorization (PMF) using the multilinear engine (ME-2) approach (Canonaco et al. 2013). This dataset was also used to test a new time-dependent source profiles evaluation to capture the variability of the sources over the year. It was achieved by performing PMF on a rolling window and allowing the algorithm to best adapt to the current data. Such approach provides very valuable improvement for long time series dataset.

This analysis revealed very contrasted seasonal OA sources contributions and pointed out the overwhelming importance of local air masses circulation. Biomass Burning Organic Aerosol (BBOA), the dominant aerosol source during winter, is advected, mainly, from inland by nocturnal breezes. In such conditions, the total PM concentration can increase by up a factor of 5 in less than 15 min. During summer the OA mass concentration is dominated by secondary organic aerosol or more precisely oxygenated organic aerosols (OOA) but the most interesting feature regards the submicron particles number concentration and their size distribution. Very intense plumes (Ntot>100 000 cm-3) of ultrafine particles (Dp<80nm) associated with SO2 are observed systematically when sea breezes bring back over the city air masses impacted by industrial and shipping emissions.

5RA.6

PM2.5 and Its Chemical Composition in Sixteen Cities in Indonesia. MUHAYATUN SANTOSO, Diah Lestiani, Syukria Kurniawati, Endah Damastuti, Indah Kusmartini, Djoko Prakoso, Dyah Kumala Sari, Philip K. Hopke, Rita Mukhtar, et al., *Center for Applied Nuclear Science and Technology, BATAN*

The seasonal and spatial characteristics of PM2.5 and its chemical composition in Indonesia have been studied over a 3-year period (2014–2016) in sixteen big cities Indonesia covering Java, Sumatera, Kalimantan, Sulawesi, Maluku and Papua islands. Samples of airborne particulate matter were collected once a week for 24 hr using a Gent stacked filter unit sampler in two size fractions of 2.5 µm (PM2.5) and 2.5 to 10 µm (PM2.5-10). Black carbon (BC) was determined by reflectance and chemical elements analysis which performed by using Energy Dispersive X-ray Fluorescence (EDXRF). The measurement of chemical composition will be focused on the heavy metals concentrations for PM2.5. The annual mean of PM2.5 ranged from 4.13 to 20.5 µg/m3. The results showed that majority of the annual concentrations of PM2.5 in Java sites exceeded the annual average air quality standards (15 µg/m3), while for other sites are lower than the standards except Pekanbaru. During the period of forest fires in 2015, the daily concentrations of PM2.5 in Pekanbaru and Palangka Raya have exceeded the daily average national standard (65 µg/m3). While during the year 2016 the incidence of forest fires in both sites considerably reduced and the maximum concentration of PM2.5 are still below the standard. The PM10 annual mean concentrations for all sites were below national standards (150 µg/m3), while the average ratio of BC concentrations compared to the PM2.5 ranged from 10 to 27 %. Chemical composition of PM2.5 were also determined in order to understand the anthropogenic source of particulate matter. The results obtained in Surabaya and Tangerang sites showed that level of heavy metals in PM2.5 significantly higher than in other sites. These several findings significantly support the national programs of air quality improvement. The results can be used as an early warning, scientific research based references in designing and revising various government policies and regulations related air quality standards in Indonesia.

5RA.7

The Extinction Coefficient of the Aerosol over the Denver Metropolitan Area: Comparison with a Historic Data Set.

HELMUTH HORVATH, Paulus S. Bauer, *University of Vienna, Faculty of Physics, AEP*

Two identical series of optical measurements with the University of Vienna Telephotometer have been performed between July 23 and August 11 in the years of 1979 and 2017. Despite of being 38 years apart the same instrument and the same visibility targets have been used. During these 38 years the population of Colorado almost doubled from 2.8 to 5.6 Million, Boulder County's population increased from 130,000 to 300,000; Broomfield's population increased by a factor of more than 3, Denver City's population increased from 520,000 to 710,000, other surrounding communities also had a considerable population growth. Since human activities are also sources of particulate and gaseous emissions an increase in emissions has to be expected. On the other hand a series of new technologies has been introduced, e.g. exhaust gas cleaning of cars, thus a reduction in emissions per capita could be expected. Comparing the two datasets allows to see the result of the two counteracting effects.

The telephotometer was positioned on Gunbarrel Hill slightly north of Boulder and the spectral radiance of Mt. Morrison, slightly Southwest of Denver, was measured. Comparing the measured radiance with the radiance of the horizon behind the mountain, the extinction coefficient along the sight path can be determined. This sight path is between 100 and 800 m above the Greater Denver Area, and definitely also influenced by emissions in this area.

The weather conditions showed considerable variability, but this was the case in both years. Measurements performed during rain or fog (if possible at all) were excluded in the analysis reported below, so humidity growth of deliquescent particles needs not to be accounted for. Sometimes considerable haze screened the target, so optical measurements were not possible. In 1979 there was one day with considerable haze, so that no observations were possible. In 2017, there was also one day with considerable haze, but on about half of the days the extinction coefficient increased during the day and in the afternoon the target was obscured. This normally occurs when the mixing layer expands due to heating of the atmosphere by insolation.

The obscuration of the target makes a comparison difficult but still some conclusions can be drawn: Based on hourly measurements between 8:00 and 17:00, in 1979 the target was invisible 12 times during the measuring period. In 2017 it was obscured 29 times.

When being visible, the average measured extinction coefficient at 550 nm in 1979 was 46 Mm^{-1} with a standard deviation of 16 Mm^{-1}. For 2017 the corresponding values are 44 Mm^{-1} ± 18 Mm^{-1}, which can be considered the same value within the fluctuations. But this is only half of the story, since times where observations could not be performed were neglected. Therefore we included the data where no measurement could be performed as 100 Mm^{-1}, which is the minimum extinction coefficient needed to obscure the target. Obviously its value could be larger, the averages reported below are minimum values. Using these values, we obtain for the 1979 period an average of 51 Mm^{-1} with a standard deviation of 22 Mm^{-1} and for the 2017 period 60 Mm^{-1} ± 29 Mm-1. This can also be considered as indication of an increase in atmospheric extinction coefficient from 1979 to 2017.

The measured aerosol extinction coefficient was wavelength dependent, for about 85 % of the measured spectral extinction coefficients the Angström approximation (the extinction coefficient being proportional to λ^{α} with α the Angström exponent) could be applied. The Angström exponent is an indication for the mean size of the particles, the smaller α, the smaller the particles.

For the measuring period in 1979 an average α of -0.87 with a standard deviation of 0.36 was found, for the 2017 period the average was α=-1.24 ± 0.3. Therefore the particles in the air of 1979 were larger than in 2017. This is reasonable, since e.g. particles emitted by modern cars have become much smaller over the years.

5RA.8

Aerosol Chemical Composition Measurements from a Ship Campaign across the Mediterranean and Middle East during the Summer of 2017. JAMES BROOKS, Eoghan Darbyshire, Frank Drewnick, Stephan Borrmann, Hugh Coe, *University of Manchester*

The Middle East is home to over 200 million people, with the majority living in urban areas. The climate is hot and arid, with climate warming significant especially in summer months. It is well known that this region suffers from intense dust concentrations, as well as other aerosol species. The Mediterranean basin is an area encompassing a variety of environments and climates, with the region susceptible to both long-range transport of atmospheric aerosol from Europe, Africa and the Middle East, as well as local sources such as ship emissions. Although the Middle East and Mediterranean regions are a global change hot spot, they have received only little attention, e.g., in reports of the Intergovernmental Panel on Climate Change (IPCC, 2013). One reason is that observational data are insufficient, unavailable or of limited quality. In the past, studies needed to rely on satellite observations and sparse meteorological data. Atmospheric chemistry data are essentially non-existent.

There is a key relationship between aerosol and atmospheric chemistry. The reactive uptake of pollutant gases by mineral compounds can drastically change the particle properties, whereas the aerosols in turn influence the gas phase chemistry. Acidic pollutants can turn the particles from hydrophobic into hydrophylic, and convert them into efficient cloud condensation nuclei (CCN) (Karydis et al., 2011). This can alter the microstructure of clouds and increase removal of the particulates by deposition processes (Abdelkader et al., 2016). These processes have been found to be of key importance for Saharan dust that is transported over the Mediterranean basin and Middle East region.

The Air Quality and climate change in the Arabian Basin (AQABA) study aims to alleviate current scientific issues with unique field measurements, combined with satellite observations and high resolution atmospheric chemistry and climate modelling. A comprehensive ship-borne campaign took place from June-September 2017 measuring gases and particles in the Arabian Basin and the Mediterranean, studying the regional contrasts that occur in the atmospheric pollutants. The results presented here are collected from an aerosol instrument called a High-Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS), which collected aerosol chemical composition measurements. The presentation will summarise the key features in the regional aerosol burden for these regions, with an analysis into the sources of air masses.

Preliminary results show stark regional changes in aerosol chemical composition across the Middle East and the Mediterranean. Early highlights are very high sulphate and ammonia concentrations from a mix of local and long-transported sources in the Persian Gulf. Long range transported, highly oxidised organics in the Indian Ocean. Nucleation events in the Red Sea, coupled with high organics and sulphate concentrations throughout, especially in the Suez Canal region. And lastly, long range organics and nitrate concentrations in the Mediterranean, appearing to be sourced from mainland Europe.

Aerosol Droplets Exhibit Stable pH Gradient. Haoran Wei, Qishen Huang, Linsey Marr, PETER VIKESLAND, *Virginia Tech*

Suspended aqueous aerosol droplets (<50 µm) are micro-reactors for many important atmospheric reactions. In droplets, and other aquatic environments, pH is arguably the key parameter dictating aqueous chemistry. The dynamic air/water interface of a droplet has the potential to significantly alter droplet pH from bulk water values. However, it is challenging to measure the pH inside single droplets due to their inaccessibility when using conventional pH meters. In this study, phosphate buffer droplets containing ≈75 nm gold nanoparticle (AuNP) based pH nanoprobes were collected onto a superhydrophobic substrate and scanned by laser confocal Raman microscopy. The Raman signal of the pH reporter, 4-mercaptobenzoic acid (4-MBA), was enhanced substantially through surface-enhanced Raman scattering (SERS) enabled by the AuNP clusters. By using these nanometer-sized pH probes the pH inside individual aerosol droplets was for the first time acquired. We show that the pH in a droplet is higher than that of bulk water by ≈3.3 pH units, which we attribute to the accumulation of protons at the air/water interface. The existence of this unexpected pH shift was corroborated by the observation that the catalytic reaction that only occur under basic conditions (i.e., dimercaptoazobenzene (DMAB) formation from 4-aminothiophenol (4-ATP)) occur within droplets, but not bulk solution. Results of three-dimensional scan also showed that the pH decreased from the droplet centroid to air/water interface. As the molar ratio of ammonia sulfate to phosphate buffer increased, the pH gradient decreased and finally was reversed indicating that the chemical compositions inside the droplet significantly affect its pH gradient.

6AC.2

Exploring Acidity in 1-10 µm Sized Liquid-Liquid Phase Separated Aerosol Particles. REBECCA CRAIG, Andrew Ault, *University of Michigan*

Secondary organic aerosol (SOA) formation and many of the subsequent multiphase chemical and physical processes SOA particles undergo are highly dependent on acidity. One such physical process is liquid-liquid phase separation (LLPS), which occurs commonly in atmospheric SOA particles. Relative humidity (RH), particle size, and chemical composition effects on LLPS have been characterized in laboratory studies, but few have focused on pH impacts on LLPS. Previous work has found that increasing pH corresponds to a decrease in the separation RH and that once LLPS occurs, the organic-rich phase is less acidic than the previously single phase particle. However, these studies have investigated primarily large particles (20-200 µm) at pH levels higher than what thermodynamic models predict for atmospheric aerosols. Herein, we investigate LLPS of laboratory-generated SOA particles composed of ammonium sulfate and polyethylene glycol 400 at atmospherically relevant sizes and pH's. Both bulk aerosol and individual particle pH are measured via established pH indicator paper and spectroscopic methods, respectively. The results of this study could have implications for acidity-dependent particle phase processes and how aerosol particle composition and morphology influence climate effects.

6AC.3

An Integrated Approach to Connecting the Chemical and Physical Properties of Aerosol. JAMES F. DAVIES, Michael Jacobs, Kevin Wilson, *University of California, Riverside*

Our ability to fully understand the effect of aerosols in the atmosphere requires a complete description of their physical and chemical state. Due to the highly oxidizing conditions in the atmosphere, aerosol particles are subject to heterogeneous oxidation, leading to their composition evolving over time. As composition evolves, so too do associated physical properties and characteristics, such as viscosity, hygroscopicity, surface tension, and diffusion. These factors regulate the ability of aerosols to act as sources of cloud condensation nuclei, influence their interactions with incoming solar radiation, and play an important role in the way aerosol affect air quality and human health.

Analytical techniques such as mass spectrometry and Raman/IR spectroscopy are powerful methods applied to measure the evolving chemical composition of aerosols and droplets. Single particle techniques, such as optical tweezers and electrodynamic balances, have been successful in measuring physical properties of aerosol particles, such as surface tension and hygroscopicity. The ability to combine these two types of measurement in a single experiment to resolve how physical properties change with an evolving sample composition could provide a fascinating new insight into how aerosol behave in the atmosphere.

Here, I report the coupling of a single particle levitator (a linear-quadrupole electrodynamic balance) to a high-resolution mass spectrometer.[1] Using electrospray-based ionization methods, the exact mass composition of single micron-sized droplets may be measured. Additionally, the physical properties of the droplets may be measured through the use of established methods, such as coalescence, isotope-exchange and humidity-cycling.[2] From these data, the physical characteristics of an aerosol can be directly linked to its chemical composition, providing a molecular-level insight into the factors that regulate the dynamics of aerosols in the atmosphere.

6AC.4

Molecularly Resolved Atmospheric Aerosol Processes Studied in Single Levitated Particles Using Electrodynamic Balance Mass Spectrometry. ADAM BIRDSALL, John Hensley, Paige Kotowitz, Andrew Huisman, Frank Keutsch, *Harvard University*

A thorough representation of how atmospheric aerosol particle composition changes over their multiday lifetimes, and the consequent effects on climate and human health, requires a detailed fundamental understanding of the physicochemical system coupling the gas and condensed phases. For instance, individual compounds partition between the gas and condensed phase or can undergo particle-phase reactions.

Laboratory studies of aerosol particles have provided an opportunity to isolate systems of interest in a highly controlled environment and study them with specialized instrumentation. One approach in laboratory studies has been to analyze single levitated particles, largely with optical analytical techniques. We have extended the utility of this technique by coupling an electrodynamic balance, a method of suspending single charged particles (radius ~10 µm) in an electric field, to mass spectrometry. With this electrodynamic balance-mass spectrometry (EDB-MS) approach, we can understand with greater molecular specificity changes in particle composition under controlled laboratory conditions. Previous proof-of-concept work demonstrated the ability of our setup to quantitatively analyze the changing molecular composition of a model system.

Here we present the results of experiments that use EDB-MS to track the molecular evolution of individual aerosol particles, over timescales comparable to those of atmospheric particles. We have implemented instrumental modifications to improve our control of the environment surrounding the levitated particle, our particle sizing measurements, and our ionization source. With this refined setup, we have studied processes with atmospheric relevance.

First, we have measured the effect of interactions between organic and inorganic compounds on activity coefficients. The extent to which interactions between organic and inorganic compounds modulate particle-phase activities, and hence properties such as effective vapor pressures, remain poorly constrained. Activity coefficients can be extracted from EDB-MS data by fitting measured evaporation rates to a previously validated kinetic model of particle evaporation. Compared to levitated single particle experiments that track particle evaporation via change in particle radius, with EDB-MS we are able to use the mass spectra to monitor the evaporation of chemically speciated compounds within a multicomponent particle.

Second, we have studied nonradical, condensed-phase chemical transformations of organic compounds in single levitated particles. With EDB-MS, it is possible to identify with chemical detail the products of particle-phase chemistry as well as quantify the rates at which the chemistry takes place, as a function of parameters such as temperature and relative humidity. Compared to studies that take place in the bulk condensed phase, single-particle studies of chemical transformations represent a more realistic sample matrix in which the coupling of chemical and physical processes (e.g., partitioning between the gas and condensed phases) can be studied and highly concentrated conditions can be accessed.

The fundamental parameters extracted from these EDB-MS experiments (activity coefficients, chemical rates and equilibria) can be implemented in models to improve our representations of processes taking place in atmospheric aerosol particles.

6AC.5

Dynamics of Liquid-Liquid Phase-Separation Using Spatial-Resolved Raman Spectroscopy of a Laser-Trapped Mixed Organic-Organic Aerosol Droplet. AIMABLE KALUME, Chuji Wang, Joshua Santarpia, Patricio Piedra, Yong-Le Pan, *U.S. Army Research Laboratory*

Aerosols play key role in different areas including atmospheric processes, combustion, drug designing, household sprays, etc. Building upon our recent studies of characterizing a single-particle by laser-trapping Raman spectroscopy, a multicomponent organic-organic microdroplet from a mixture of diethyl phthalate (DEPh) and glycerol (1:1 initial volume ratio) suspended in air was investigated. Initial position-resolved examination of the droplet shows a gradient concentration at different positions within the droplet, suggesting phase separation. An extensive Raman spectroscopy measurement combining spatial and temporal resolutions, revealed the phase separation and the evaporation dynamics from the droplet. The DEPh–glycerol droplet presents a typical core-shell morphology, with a glycerol-rich core and DEPh highly concentrated within the outer layer. The reported approach provides a direct experimental observation of the morphological structure and the chemical microcomposition of a multicomponent microdroplet suspended in the ambient air. This technique opens new doors in probing surface enhanced phenomena, such as potential chemical reactions taking place at the interface of aerosols with the chemicals in the surrounding microenvironment.

6AC.6

Measurements and Modelling of Surfactant Coated Aerosol Particles. BRYAN R. BZDEK, Jussi Malila, Nonne Prisle, Jonathan P. Reid, *University of Bristol*

The surface tension of atmospheric particles is key to determining the critical supersaturation required for a particle to activate into a cloud condensation nucleus. Most models generally assume the surface tension of activating particles is equivalent to that of pure water. However, recent experiments have shown that the surface tension of particles can be much less than that of pure water, for instance due to the presence of condensed organic films, core-shell phase separations, and/or surfactants. Indeed, recent field studies have indicated that surfactants are important components of organic aerosol composition. For surfactants to be relevant to particle activation into cloud droplets, at least two parameters must be considered. First, the concentration of surfactant in the initial particle must be sufficiently large that surface tension depression is maintained over the course of activation, despite the dilution that occurs as water condenses onto the particle. Second, the high surface to volume ratio of micron and submicron particles necessitates partitioning of more surfactant molecules to the particle surface than in a typical solution, resulting in a depletion of the bulk concentration and an increase in the surface tension relative to a bulk sample.

This presentation will provide a comprehensive account of the size dependent partitioning behaviour of surfactant containing particles through a combination of measurements and modelling. The experimental approach utilises holographic optical tweezers, which allows quantification of the surface tension of picolitre volume surfactant-containing droplets. The measurement is accomplished by sub-microsecond resolved monitoring of the periodic shape oscillations resulting from controlled coalescence of two optically trapped droplets. Surface tensions are resolved to <1 mN/m. These experiments, when compared to bulk tensiometry measurements, demonstrate the surface-bulk partitioning effects in micron-sized droplets. Indeed, surface-bulk partitioning can result in a difference of >10 mN/m between the droplet measurement and the bulk measurement at the same nominal concentration. The experimental data are compared to a surface monolayer model that is constrained only by bulk surface tension measurements. This model agrees well with experimental observations, providing confidence in its treatment of particle surface-bulk partitioning. As a result, particle surface tension can be modelled to determine the sensitivity of particle surface tension to particle size and surface tension. This approach therefore will provide key information about the significance of the surface tension assumptions inherent in climate models.

6AC.7

Exploring Chemistry in Microdroplets in a Branched Quadrupole Trap. MICHAEL JACOBS, James F. Davies, Ryan Davis, Lance Lee, Frances Houle, Kevin Wilson, *Lawrence Berkeley National Laboratory*

Reactions in compartmentalized spaces are ubiquitous in nature, occurring in cells, mineral pores and aerosol droplets in the atmosphere. Recent studies have probed chemical reactions in a variety of different compartmentalized spaces, such as in an electrospray source, oil water emulsion, and thin films. These studies suggest that reactions in micron-sized compartments can occur at rates that are enhanced by several orders of magnitude compared to similar reactions in bulk solution. The experimental rate enhancements have been attributed to several different sources: increased concentration of reactants due to solvent evaporation, extreme pH in compartments due to large amounts of charge on the droplets, and interfacial effects due to the large surface to volume ratio of the compartments. While each of these explanations may play a role, a general explanation and the relative importance of each remains unclear. Ultimately, the source and generality of the observed rate enhancements has potentially far reaching implications for condensed phase aerosol chemistry as well as origin of life chemistry.

Here, I report work that has been performed using a recently developed single particle levitator (a branched quadrupole electrodynamic trap)[1] to study reactions occurring in micron-sized droplets. Using this trap, two 20-50 µm droplets with different compositions are contactlessly manipulated and merged to initiate a chemical reaction. Both the composition and size of the merged droplet are controlled precisely in the trap, and the evolving reactions within the droplets are probed spectroscopically (Raman) or with single particle mass spectrometry. From these measurements, the role of the air-water interface is isolated from concentration and pH effects, and its relative importance in enhancing reaction rates is determined.

6AC.9

Validating a Surface Concentration Model. Anthony Toribio, Nonne Prisle, ANTHONY S. WEXLER, *University of California, Davis*

In 2013, Wexler and Dutcher published a paper using statistical mechanics to derive an expression for the surface tension of solutions over the full range of concentration from pure solvent to pure solute. The model only has a few free parameters yet was able to fit surface tension data for a wide range of organic and electrolytic solutes in water. In the current work we used the expression derived by Wexler and Dutcher along with the Gibbs adsorption isotherm for multicomponent systems to derive expressions for surface excess concentration. The parameters in the surface tension equation are the same as in the surface concentration equation, so if measurements are available for surface tension as a function of solute activity, the parameters can be identified and used to predict the surface concentration. In 2015 and 2016, Walz and coworkers published some of the first measurements of the surface concentration of alcohols on water; X-ray photoelectron spectroscopy was used to make the measurements.

In the current work, the derivation of the surface concentration equation is presented and the surface concentration predictions are compared with the measurements of Walz for 1-butanol, 1-hexanol, 1-pentanol, 1-heptanol, and t-butanol. The comparison sheds light on the model and measurements, but also on the meaning of surface excess concentration.

6AE.1

Characterization of Air Pollutants in Delhi during 2017. HAO GUO, Shovan Sahu, Sri Kota, Hongliang Zhang, *Louisiana State University*

Delhi is facing severe air pollution and the government has set up air pollutant monitoring network to inform the public and increase the understanding of air pollution events. One year-long air pollutants data collected from the network were analyzed in this study. This is the first time to the spatial and temporal variations of particulate matter with aerodynamic diameter less than 2.5 µm (PM2.5) and less than 10 µm (PM10) as well as gaseous species were studied in Delhi using hourly data from 8 sites during 2017. Delhi is facing tremendous air pollution as all major pollutants have concentrations reaching severe pollution levels. Seasonal variations are analyzed and correlations between different pollutants and same pollutants at different sites are investigated. In addition, three extreme PM2.5 events (hourly average concentration exceeding 300 µg/m3 for ~40 hours) are examined with the consideration of meteorological conditions. This study can greatly support the research on formation, transport and human health effects of air pollutants in Delhi and India.

6AE.2

Particulate Matter Concentrations from Urban Settings of Pakistan, China and Europe (UK). IRFAN ZAINAB, Zulfiqar Ali, Zona Zaidi, Syed Turab Raza, Zaheer Ahmad Nasir, Ian Colbeck, Liu Weilong, *University of the Punjab, Lahore, 54590, Pakistan*

Continental blanket of particulates over cities is disturbing sun energy trapping and grosses to atmosphere. Particulate matter (PM) is also the key component of air pollution that is directly thrown into the air by various natural and anthropogenic sources. Exposure to particulate air pollution has directly been associated to higher morbidity and mortality. Studies show that particulate matter is one of the six criterion pollutants and the most dangerous one accounts for 3.7 million premature deaths annually and nearly 88 percent of these deaths occurs in developing countries. Current investigations reveals indoor and ambient PM levels monitoring in urban settings of the major cities from UK, Pakistan and China. Student accommodations, public transports, and ambient residential settings were selected as study areas. Particulate matter emissions were monitored for twenty-four hours at each site except transport indoors monitoring that was for six hours. Latest DustTrak DRX (Model 8533, TSI Inc.) recently calibrated was used that simultaneously give the values of all fractions like PM_1, $PM_{2.5}$, PM_4 Respirable, PM_{10} and PM_{Total}. The findings conclude that the respective average values for PM_{Total} concentrations for Student accommodations in UK (61 μg/m³) was much lower than the rest of monitored countries with overall average, Pakistan concentrations (372μg/m³) was remarkably higher, while China was also found to be significantly polluted with 223μg/m³ of Particulate matter. On the other hand, Public transports were also monitored that showed remarkably higher level of PM concentrations with average PM_{Total} concentrations of 87 μg/m³ in UK, (372 μg/m³) in Pakistan and 151 μg/m³ in China. These persistent elevated PM concentrations shows the Ambient PM concentration levels have influenced indoor buses and transport facility that is serious health concerns for passengers. The ambient environment of UK, Pakistan and China results were supporting evidence with monitored respective values of PM total were 45 μg/m³ in UK, 121 μg/m³ in Pakistan and 110 μg/m³ in China. Weather and climatic conditions are not similar in these countries that certainly have influenced the fluctuations in the PM concentrations despite of other factors. Therefore, the origin and source of PM is alarming with significantly high figures than the air quality standards suggested by the WHO limits.

6AE.3

Secondhand Smoke Exposure during the Travel between United States and China: The Association with Urinary Biomarkers of Polycyclic Aromatic Hydrocarbons and Lipid Peroxidation. Yan Lin, Xinghua Qiu, YIFANG ZHU, *University of California Los Angeles*

Secondhand smoke (SHS) was among top risk factors to general population. Exposure to SHS might vary among countries due to different smoking prevalence and control policies, but it is unclear whether cross-border traveling would bring significant health risk from SHS exposure to international travelers. In this study, we followed 27 non-smokers traveling between Los Angeles and Beijing. Their urine samples (n=196) were collected before (LA1), during (BJ), and after (LA2) the trip for the measurement of biomarkers of SHS (i.e. cotinine), polycyclic aromatic hydrocarbons (PAHs) and lipid peroxidation (i.e. malondialdehyde and 8-isoprostane). The geometric mean concentration of urinary cotinine was 0.13, 1.50, and 0.22 µg/g creatinine in LA1, BJ and LA2, respectively. Likewise, hydroxylated-PAHs (OH-PAHs) were also significantly higher in BJ than LA1 or LA2 ($p<0.05$). The increase of urinary OH-PAHs in BJ was partially attributed to SHS exposure given its significant association with urinary cotinine ($p<0.05$). Urinary cotinine was positively associated with malondialdehyde and 8-isoprostane ($p<0.05$). These results indicated an increase of SHS exposure caused by the travel from Los Angeles to Beijing, which might further contribute to an increase in PAHs exposure and lipid peroxidation.

6AE.4

Vertical Variations in Outdoor Particulate Matter along the Height of a Tall Building in an Urban Environment.

PARHAM AZIMI, Haoran Zhao, Torkan Fazli, Dan Zhao, Afshin Faramarzi, Luke Leung, Brent Stephens, *Illinois Institute of Technology*

It is generally assumed that building height can affect indoor exposures to pollutants of outdoor origin in tall buildings, as some ground-level pollutants such as particulate matter may be diluted at higher elevations. However, we are aware of very few measurements of airborne particle concentrations that have been made along the height of tall buildings. Therefore, we conducted a pilot study to measure the vertical variation of environmental conditions, outdoor particulate matter, and several other outdoor pollutants along the height of a ~60-story (~300 m) building in downtown Chicago, IL during a one-week period in the summer of 2017. Simultaneous measurements of size-resolved particulate matter (0.3 to 10 µm, which were used to estimate PM1, PM2.5, and PM10 mass concentrations), were made using multiple sets of instrumentation installed in the outdoor air intakes of the mechanical systems on the 2nd, 16th, 29th, and 44th floors and in an open-air area on the 61st floor. The results demonstrate that PM1, PM2.5, and PM10 concentrations generally decreased approximately linearly with building height. The vast majority of measured differences were statistically significant. Most strikingly, the average PM1 and PM2.5 concentrations on the top two floors were more than 30% lower than on the 2nd floor. Moreover, we used a simple well-mixed mass balance model to demonstrate how the measured differences in particle concentrations along the height of the test building would likely manifest in differences in indoor concentrations of particles of outdoor origin in a typical office space.

Assessment of Personal Exposure to Particulate Emissions in Urban Microenvironments. Jie Rui Ngoh, Thi Minh Phuong Tran, RAJASEKHAR BALASUBRAMANIAN, *National University of Singapore*

Fine particles suspended in air (PM2.5) pose a threat to public health due to their ability to penetrate deep into the respiratory tract and migrate into the bloodstream. As a result, finding the sources of these particles and controlling their emissions are a top priority in many countries. Fixed air quality monitoring stations, equipped with expensive and bulky instruments, are widely used to measure PM2.5. However, these instruments have limitations because of their fixed positions and do not provide spatially representative PM2.5 readings. Furthermore, the PM2.5 concentrations provided by a single monitoring site may not accurately represent the particle concentrations around people distributed in its vicinity, who may be concerned about the health effects of PM exposure. Mobile and cost-effective PM2.5 sensors been developed in recent years to overcome this problem and to provide realistic data for human exposure assessment and urban air quality improvement.

We carried out a pilot study to assess personal exposure to mass concentration of PM2.5, sub-micron particle number concentration, Np, and equivalent Black Carbon, eBC, in diverse outdoor and indoor microenvironments (MEs) in Singapore, a densely populated country. A GPS receiver was used to track movement and exposure of individuals across the MEs. The novelty of this approach is that exposure measurements were taken across the full heterogeneity of places visited and activities conducted to gain as much insight as possible into an individual's total exposure. This is important as individuals are constantly on the move and follow their own activity patterns, which determine their individual exposure. Exposure to PM2.5, Np, and eBC varied considerably across the MEs because of changes in the particulate emissions from local sources in the immediate vicinity of MEs. Personal exposures to PM2.5 based on the data obtained from portable sensors were much higher those from fixed air quality monitoring stations. Mobile sensing could thus provide local environmental protection agencies with a comprehensive map of PM concentrations, at specific locations and at specific times, which allows for formulation of effective strategies to reduce PM emissions at the city scale.

6AE.6

Neighborhood-scale Spatial Variability of PM Mass and Number and Exposure Misclassification in an Eastern US City.

Hugh Li, Peishi Gu, Qing Ye, Naomi Zimmerman, Ellis Shipley Robinson, R. Subramanian, Joshua Apte, Allen Robinson, ALBERT A. PRESTO, *Carnegie Mellon University*

Long and short-term exposure to airborne pollutants are associated with adverse health effects. Regulatory monitors can be used to determine if their surrounding regions meet regulatory standards of air pollution. Measurements at monitors describe surrounding residents' air pollution exposure, help derive exposure dose response functions in epidemiology studies, and are essential input for chemical transport model and remote sensing. But evaluation is needed to assess spatial representativeness of monitors in different environments. We measured CO (traffic source marker), NO_2, ultrafine particle concentration (UFP), and PM_1 with a mobile laboratory in a post-industrial U.S. Eastern city (Pittsburgh, PA) in 2016. We sampled in ~1 km^2 areas in 15 neighborhoods representing different land use and exposure regimes (e.g., urban and rural, high and low traffic). Mobile sampling was conducted on up to 15 distinct days in each neighborhood to study fine-scale spatial variation in pollutant concentrations. Each 1 km^2 neighborhood was subdivided into 50 m cells for spatial analysis. CO and NO_2 exhibited within-neighborhood (~1 km^2) spatial variation, with hotspots elevated by up to a factor of 5 above the regional background. UFP was the most variable, with spatial variations up to an order of magnitude higher than background. PM_1 showed the least spatial variability. Spatial variability is driven by local sources, such as traffic at urban sites.

Mobile measurements convolve spatial and temporal variations in concentration, and we use multiple methods to separate these sources of variability. First, we compare observed spatial variations within each 1 km^2 neighborhood to typical hour-to-hour variations measured with a stationary monitor placed in the neighborhood. Spatial differences outside the interquartile range of hourly temporal differences are deemed significant. This analysis indicates that using a single monitor to represent the surrounding ~1 km^2 areas could introduce an average daily exposure misclassification of 46 ppb (S.D. = 26) for CO (30% of regional background), 3 ppb (S.D. = 2) for NO_2 (43% of background), 4000 #/cm^3 (S.D. = 1900) for UFP (64% of background), and 1.2 μg/m^3 (S.D. = 1) for PM_1 (13% of background). Exposure differences showed fair correlation (R^2 = 0.5) with traditional land use covariates such as traffic volume and restaurant density. Secondly, we used Wilcoxon signed-rank test to determine which 50 m cells represent the same underlying distribution of concentrations, and which are different. This test allows us to examine the robustness of our exposure misclassification calculations, and to determine the number of monitors required in each neighborhood to reduce pollutant exposure misclassification within 10%.

6AE.7

Early Lessons from New Air Pollution Exposure Science: High-resolution Mapping of Urban Air Quality using Google Street View Cars, Low-cost Samplers, and Aerosol Mass Spectrometry. JOSHUA APTE, Kyle Messier, Sarah Chambliss, Michael Brauer, Julien Caubel, Shahzad Gani, Steven Hamburg, Thomas W. Kirchstetter, Julian Marshall, Brian LaFranchi, Melissa M. Lunden, Chelsea V. Preble, Albert A. Presto, Christopher Portier, Allen Robinson, Ellis Shipley Robinson, Rishabh Shah, Karin Tuxen-Bettman, Roel Vermeulen, Ramon Alvarez, *University of Texas at Austin*

Human exposures to air pollution can vary sharply in space and time. Recent advances in measurement technology enable a rich understanding of the spatiotemporal patterns of outdoor air pollution that influence population exposures and environmental inequities. For example, carefully designed mobile sampling campaigns are now able to reveal patterns of long-term ambient air pollution concentrations at very fine scales (<< 100 m).

Here, we present an overview of the most extensive mobile air pollution measurement campaign conducted to date in a single urban area. Using two specially equipped Google Street View cars, we mapped spatial patterns of air quality in the San Francisco Bay Area between May 2015 and December 2017. The cars were outfitted with reference-grade instruments to measure NO, NO_2, black carbon (BC) and ultrafine particle number count at high time resolution (~ 1 Hz). During a 30-month campaign, measurements took place on most weekdays during daytime hours, resulting in a large dataset: ~10 million samples collected during > 4000 h, encompassing 100,000 km of driving. Additional sampling incorporated a dense network of low-cost samplers and a mobile aerosol mass spectrometer, as described below. The overall campaign consisted of several targeted investigations.

During an initial year of already-published measurements, we sampled every road 20-50× within three neighborhoods (~30 km^2) in Oakland, CA. Next, during 1.5 years of follow-up measurements, we mapped pollutant concentrations in rural, suburban, and dense urban neighborhoods throughout the SF Bay Area. These measurements reveal how the within-neighborhood pollution structure is overlaid on top of regional spatial gradients in air quality. Repeated measurements over the full 2.5-year period demonstrate persistent spatial variability over time. Patterns of NO, NO_2 and BC in Oakland had high correlation (r^2>0.85) between the first and second years of measurements. Shorter-term measurement periods (~1-2 months) were generally sufficient to reproduce overall spatial patterns, albeit with ±30% bias in mean concentrations relative to annual-average conditions.

We conducted an especially intensive multi-method study of the mixed residential/industrial West Oakland neighborhood during Summer 2017. Street View cars drove every street in this 5 km^2 domain during days, nights, and weekends to characterize the temporal evolution of spatial patterns in air quality. In parallel, a dense network of 100 BC monitors was deployed at fixed sites to characterize temporal patterns at fine spatial scales. Finally, a van with a high-resolution aerosol mass spectrometer (HR-ToF-AMS) repeatedly sampled all city streets in the same domain to collect data on non-refractory PM_1 chemical composition. We used positive matrix factorization of AMS data to identify source signatures that contribute to spatial patterns of air quality. Fixed and mobile measurements indicated that BC, NO, and other primary species were elevated on weekdays relative to weekends, with distinct shifts evident in spatial patterns within neighborhoods. UFP concentrations were less spatially variable, and exhibited a pronounced mid-day peak with only small weekday-weekend differences. Mobile AMS data demonstrate a temporal evolution of source and background contributions over the course of each day and spatial hotspots with elevated markers of primary emissions.

This campaign overview presentation (i) summarizes how routine mobile air pollution monitoring can reveal new information about spatial variability in population exposure to air quality, (ii) explores the methodological advantages and tradeoffs of alternative sampling approaches, and (iii) illustrates how established measurement techniques from the atmospheric sciences can add powerful new insights to studies of human exposures in urban areas.

6AE.8

Child Exposure to Indoor and Outdoor PM at Schools and Homes in the Lisbon Metropolitan Area, Portugal. VÂNIA MARTINS, Susana Marta Almeida, Tiago Faria, Inês Cunha-Lopes, Carolina Correia, Nuno Canha, Evangelia Diapouli, Manos Manousakas, Konstantinos Eleftheriadis, *C2TN, IST, Universidade de Lisboa, Portugal*

Numerous personal exposure studies have revealed poor correlations between outdoor ambient PM concentrations and personal exposure measurements. In fact, the personal exposure includes not only contributions from ambient PM sources, but also contributions from indoor, commuting and leisure activities, which depend on the lifestyle of each individual and the different microenvironments frequented, such as home, workplace, commuting type, etc. Since people spend most of their time (80 – 90%) indoors, it is widely recognized that a significant portion of total personal exposure to ambient PM occurs in indoor environments. Whilst the health effects of adult exposure cannot be neglected, children are more susceptible than young adults to air pollutants; therefore, their exposure is a major health concern.

This study aims to assess the indoor and outdoor PM concentrations at several schools and homes in the Lisbon metropolitan area (Portugal) to calculate the children exposure. In the scope of the European Project LIFE Index-Air, PM2.5 and PM2.5-10 samples were collected in parallel in the indoor and outdoor of 40 homes and 5 schools. Sampling was carried out during the occupied time: 8h at schools and 15h at homes. Once the gravimetric determination of the PM mass concentrations was performed, the chemical characterization of the PM collected on the filters was carried out. The elemental analysis of PM samples was performed with a high-resolution energy dispersive X-Ray fluorescence spectrometer; the elemental carbon and organic carbon fractions of PM was analyzed by a thermal–optical method, and Polyaromatic Hydrocarbons were analyzed by gas chromatography–mass spectrometry. After the chemical composition of PM the exposure of children to PM components was assessed.

In the absence of indoor air legislation for PM, the values found in this study can only be compared with limit values for ambient air. As indoor air quality is an important determinant of human health and comfort it is essential to establish regulations for indoor microenvironments. Generally, the PM2.5 and PM10 concentrations obtained in the outdoor spaces of the homes and schools were below the WHO guidelines.

LIFE Index-Air project (www.lifeindexair.net) is developing an innovative, versatile and modular policy tool that establishes a relation between children exposure to PM compounds, health effects and emission sources. This tool combines a pack of models to select cost-effective improvement measures to protect human health. The exposure module of the tool calculates exposure from outdoor PM levels, indoor-to-outdoor concentrations and time activity patterns.

This work is funded by LIFE Index-Air Project (LIFE15 ENV/PT/000674). C2TN/IST authors gratefully acknowledge the FCT support through the UID/Multi/04349/2013 project.

Descriptive Characterization of Personal Exposure to Fine and Ultrafine Particle Among Inner-City Children with Asthma. Ehsan Majd, KIRSTEN KOEHLER, Meredith McCormack, Nadia Hansel, *Johns Hopkins School of Public Health*

Introduction: It is yet to be determined which property (size, chemical composition, morphology) of particulate matter (PM) air pollution contributes most to its adverse respiratory effects. However, recent toxicological findings point to the potentially greater role of the smaller fraction of PM, known as ultrafine particles (UFP, particles with diameter less than ~0.1 µm). Recent advances in sensor technologies has facilitated the assessment of personal exposure to UFP at high spatial and temporal resolutions; an important step towards a better characterization of PM exposure and informing effective practices and policies to mitigate its harmful effects.

Methods: In this work we characterized personal $PM_{2.5}$ (particles with diameter less than 2.5 µm) and UFP exposures of 25 children aged 8-17 with asthma for 4 consecutive days at high spatial and temporal resolutions, aiming to answer two questions: 1) is personal exposure monitoring necessary for UFP in addition to $PM_{2.5}$? 2) is it necessary to monitor personal exposures at high temporal resolution? Personal $PM_{2.5}$ and UFP (expressed as LDSA, lung-deposited surface area) monitors were placed inside a backpack, which also contained a GPS and a data logger for collecting real-time information on geographic location, temperature, relative humidity, acceleration and light intensity at 10-sec intervals. Information about means of transportation used, places visited, and activities at home that may have resulted in high exposures were also obtained. We partitioned the measured personal exposures into five microenvironments (ME): home, school, vehicle commute, walk, and other (for the visited places other than home and school) and examined the distribution of exposures in each of them for different averaging times. We also calculated and examined the correlation coefficients between $PM_{2.5}$ and UFP exposures across the MEs.

Results: Among the MEs, both $PM_{2.5}$ and UFP exposures were dominated by home. Unlike $PM_{2.5}$, time-weighted averages of UFP exposure were high for vehicle commute (35±31 $\mu m^2/cm^3$) and walk (20±11 $\mu m^2/cm^3$) relative to home (37±23 $\mu m^2/cm^3$), despite very small fractions of time spent in these MEs (averages of 1% and 2%, respectively compared to 73% for home). Mean exposures did not vary much by changing the averaging times, but we observed drastic decreases in maximum $PM_{2.5}$ and UFP exposures by increasing the averaging time from 1 to 5 min for vehicle commute and other. Correlation between UFP and $PM_{2.5}$ exposures were generally high at home (R=0.72) and poor in other MEs. However, we observed several cases of weak correlations for home (high UFP and low $PM_{2.5}$), which occurred during the evening hours and coincided with common household activities, such as cooking and cleaning (sweeping, vacuuming, and using chemical cleaners).

Conclusions: Our findings suggest the importance of personal exposure monitoring at high temporal resolution and accounting for short peaks in urban environments. Moreover, we observed that personal UFP exposure was much more sensitive than $PM_{2.5}$ to activities inside an ME, as well as moving from one ME to another. Therefore, and considering its potentially greater health risks, we believe it is crucial to include UFP as one of the major variables of interest to personal exposure monitoring campaigns, especially for more susceptible population such as children with asthma.

A Computational Study of Electrostatic Focusing of Aerosol Nanoparticles Using A 3-Electrode Einzel Lens. RAYHAN AHMED, Ranganathan Gopalakrishnan, *The University of Memphis*

The focusing and deflection of electrons and ions using electric fields has been successfully harnessed for many applications and instrumentation development. An adjustable electric field can manipulate the flight path of an electron, ion or a charged particle. This study explores the possibility of focusing charged aerosol nanoparticles, which are much heavier compared to electrons and ions. The study revealed that charged nanoparticles could also be focused towards a focal point by applying an adjustable electrostatic field along the flight path of the same. This study introduces a non-dimensional parameter χ_e ($ne\Delta V/mU^2$), the ratio of electrostatic potential energy to the kinetic energy of an aerosol nanoparticle that greatly affects focusing performance. In the absence of collisions with gas molecules (vacuum), the sum of kinetic and potential energy of a particle remains almost constant, and the applied electrostatic field controls the direction of motion. In this study, the focusing device is a 3-electrode electrostatic lens where the electrostatic field deflects particle trajectories towards the central axis of the lens. The average focal length of the lens is seen to have an inverse power relationship with χ_e (i.e.) when χ_e is almost zero the focal length is infinity and decreases with the increasing χ_e. Multiple focal points appear when electrostatic potential energy is much larger than kinetic energy ($\chi_e > 3$ in this study). The focusing performance also depends on the electrostatic lens geometry and the attributes of the inlet particles - initial kinetic energy, direction of motion and particle beam radius at the entrance of the electrostatic lens. Similar to electron and ion optics, the focusing performance is limited by spherical aberration and beam divergence. Both χ_e and initial beam width seems to maintain a cubic relationship with spherical aberration, and the divergence angle has a quadratic relationship with χ_e which ultimately increases the spherical aberration. From this study, it can be inferred that better focusing performance i.e. a tighter beam of nanoparticles with minimum spherical aberration and small divergence angle could be achievable while $\chi_e<1$, initial particle motion is parallel to the central axis, and initial beam width is much smaller compared to the diameter of the focusing device. The generation of highly focused beam of nanoparticles is motivated by nano-pattern fabrication research that has numerous applications in electronic and plasmonic devices.

6AM.2

A Binary Nucleation Model for Engineering Layered Drug Nanoparticles from Air Jet Atomization of Two-Solute Solutions.

Y.S. MAYYA, Chandra Venkataraman, *Indian Institute of Technology Bombay*

It is well-known that the use of nanoparticles for drug delivery offers several advantages in terms of targeting the delivery and enhancing bioavailability, half-life and stability in biological systems. Encapsulation of drugs in lipids often enables multidrug (hydrophobic and hydrophilic) therapy and controlled release. Aerosol synthesis of layered, lipid-encapsulated drug nanoparticles, with surface stabilizing molecules, has recently been carried out through spontaneous self-assembly in evaporating sub-micron droplet aerosols generated through air-jet atomization of two-solute solution precursors. Air-jet atomization offers higher throughput rates of nanoparticles, over that from traditional electrospray systems, with coaxial geometries, used for layered nanoparticle preparation. A major question that needs to be addressed is whether it is possible to engineer encapsulation, in a selected lipid-drug system and control layer thickness and composition. In a recent theoretical paper, (Sapra et al. 2017) an attempt was made to answer this question by introducing a novel concept of "lipid-drug demarcation diagrams". The theoretical approach employed above consists of an evaporating droplet-solute diffusion model combined with a prescription of critical supersaturation solubility (CSS) for crust formation. Critical supersaturation solubility is determined from the criterion proposed by He et al. (2006), invoked from classical nucleation theory. A parameter space was defined of material properties and process conditions for the formation of a layered structure with the preferential accumulation of the lipid in the outer layer. The developed diagrams can guide the selection of solvents, lipids, and processing conditions such that drug loading and lipid encapsulation are optimized in large scale production of layered nanoparticles. However, the CSS concept is applicable strictly for single solute system. For nucleation in a two-solute system, the attainment of crust for one species will be influenced by the activity of the other. To take this aspect into account, it is then necessary to address the problem from binary nucleation framework. In this work, we develop a theory that combines binary nucleation process (Seinfeld and Pandis, 2006) inside the droplet, with the evaporating droplet-solute diffusion model model. It involves the formation of a compound two-species critical nucleus that rapidly grows into a crust by surface growth mechanisms. The composition of the outer layer is now quantified in terms of relative enrichment of lipid over the drug. The model predicts the kinetic growth of this layer until the porosity decreases to a level when the evaporation rate slows down considerably, when the model terminates to calculate nanoparticle diameter and shell thickness. Although complex, the model not only predicts the crustal diameter, but also delineates the propagation of solidification inside the particle along with the evolution of composition. Details will be presented substantiating improvement of this approach over existing solute diffusion models.

Numerical Model for the Aerosol Formation Process in an Electrically Heated Tobacco Product. MARKUS NORDLUND, *Philip Morris Products S.A., Switzerland*

Philip Morris International is developing a range of products that have the potential to reduce individual risk and population harm compared with continued smoking. One of these products is the Electrically Heated Tobacco System (EHTS) (also referred to as the Tobacco Heating System 2.2), which is currently commercialized in more than 30 markets. During use, the patented EHTS heats a specifically designed tobacco product (Electrically Heated Tobacco Product (EHTP)) without combustion when inserted into the Holder (heating device). The EHTP contains a specially manufactured tobacco material in the form of a porous plug that undergoes a controlled heating process to release chemical compounds (present in the tobacco material) into vapors. As there is no combustion of the tobacco substrate, no smoke is formed, and the nicotine-containing respirable aerosol is instead formed with the help of an aerosol former (glycerol) added to the tobacco material.

The aim of this work was to numerically model the aerosol formation process for realistic operating conditions of the EHTS and for relevant gas-vapor mixture compositions measured in the generated EHTP aerosol. Chemical analysis of the EHTP aerosol showed that it consisted mostly of water, glycerol, and nicotine as well as other compounds at much lower concentrations. An extended Classical Nucleation Theory (CNT) for multicomponent gas-vapor mixtures was used to numerically model the aerosol formation taking place in the EHTP during use when operated in the Holder. Cases with and without glycerol present in the tobacco substrate were simulated to specifically investigate the role that glycerol plays during the aerosol formation process.

Results from the performed numerical simulations demonstrate that glycerol was the compound triggering aerosol formation under the simulated operating conditions of the EHTS and EHTP. Water and other compounds in the gas-vapor mixture were not able to reach supersaturation and therefore could not generate aerosol droplets from the multicomponent gas-vapor mixture at the operating conditions simulated. This implies that according to the extended CNT, an aerosol will only form under the tested operating conditions when there is an aerosol former, such as glycerol, present in the gas-vapor mixture.

A Multiscale Model for Evolving Multispecies Aerosol Deposition and Absorption in the Human Lung. Ravi Kannan, Z.J. Chen, ANDRZEJ PRZEKWAS, Florian Martin, Julia Hoeng, Arkadiusz Kuczaj, *CFD Research Corporation*

Computational fluid dynamics (CFD) models able to predict aerosol transport, evolution and deposition are useful in supporting and predicting in vitro and in vivo aerosol exposure and dosimetry results. Their ultimate goal of development and application would be to become integrated with in vitro bio-fluidics and in vivo physiological responses of the studied systems (e.g., CFD-PBPK linked approaches). The required level of sophistication of such mathematical models depends on the specific application. It is also often limited by the computational complexity of the respiratory system anatomy, and physiology. Detailed CFD aerosol deposition models are typically used for the trachea and upper bronchi, due to their high computational complexity and cost, while the approximate whole-lung models, such as the Typical Path Lung model, have issues concerning their application and accuracy.

To overcome the above mentioned barriers we have developed a novel multiscale computational model of human lung respiration physiology, including the inhalation of aerosols and their deposition on the airway walls followed by absorption and clearance via mucosal and alveolar barriers. In the conventional aerosol inhalation simulations, the airways are generally split into the upper airways and alveolar sections. Such “compartmental” models result in low-resolution results and the spatial resolution of the deposited aerosol cannot be accurately calculated. The foundation of the present multiscale model is the high-resolution anatomical geometry of a human entire respiratory tract from the mouth to the alveolar zone.

A two-step computational algorithm is used to predict the aerosol deposition. In the first step, high-fidelity 3D CFD simulations, on the adaptive Cartesian mesh, are performed to simulate air flows and transport of aerosol and gaseous compounds of the aerosol mixture. The spatial lung airway wall deposition patterns are computed and stored. In the second step, a novel, computationally efficient Quasi-3D (Q3D) airway wall barrier model is used to simplify the geometry and simulate both mucociliary and trans-mucosal absorption of the deposited compounds. The Q3D method preserves the 3D geometrical structure, delivering extremely accurate solutions and being approximately 25000 times faster than CFD methods. The Q3D lung airway model is then populated to around 15 generations (tracheo-bronchial limit). The alveolar region can be modeled using simplified bolus-type sacs matching the alveolar surface area, at the end of each bronchial leaf.

In the present multiscale model, the 3D CFD method is used to simulate the aerosol transport/deposition up to the first three airway generations. The Q3D model is then used to simulate aerosol transport/deposition in the distal airways. The resulting deposition is then used as the airway barrier model to simulate deposited aerosol mucociliary clearance and trans-mucosal absorption. The resulting mucociliary model is first implemented and validated against the experimental clearance results, involving non-absorbing radiolabeled particles. The paper presents selected validation results for the aerosol transport, deposition, and clearance in the lungs and comparison between previously published models and available experimental data.

Numerical Study of Flow Rate Effect on Hygroscopic Aerosol Transport and Deposition in a Basic Mouth-throat Airway with Realistic Wall Conditions. XIAOLE CHEN, Clement Kleinstreuer, Yu Feng, Tong Lu, Baobin Sun, Wenqi Zhong, *Southeast University*

Using an idealized mouth-throat (MT) airway as a test bed, simulations were carried out to investigate the impact of flow rate on hygroscopic aerosol transport and deposition (Longest et al., 2010). Specifically, a multi-layer structure, including the airway tissue and mucus layer, was constructed to simulate heat transfer across the MT boundary layer, i.e., conduction in the mucus layer and tissue, latent heat loss due to mucus evaporation, and convection over the mucus layer. The transport and deposition of the hygroscopic aerosols was simulated with a validated numerical program at three flow rates, i.e., 15 L/min, 30 L/min, and 60 L/min. The aerosols contained four components: water, ethanol, sodium chloride (NaCl), and fluorescein. The transition shear stress transport (SST) model and discrete phase model (DPM) were employed for the prediction of the air flow and aerosol transport, respectively. Modeling and validation of the aerosol deposition efficiency and aerosol-vapor interaction are discussed in our previous study (Chen et al., 2017).

The temperature of the tissue boundary toward the body surface side was set at 37 ˚C. The temperature of the mucus layer, which decides the saturation pressure of the water vapor, was determined by the heat transfer conditions, i.e., mucus evaporation, convection of the air and the conduction between the mucus layer and airway tissue. The air inhaled was assumed to be at room conditions, i.e., 26.7 ˚C and RH = 34%. For each flow rate, simulations with various initial aerosol diameters ranging from 2µm to 20µm were conducted to obtain the functional dependence between the aerosol deposition efficiency and the Stokes number.

The results are as follows:

1) Significant temperature gradients can be observed in the mucus-tissue region due to the latent heat loss of the mucus layer and convection along the air-mucus interface; especially under elevated flow rates.

2) The multi-component aerosols quickly evaporate in the relatively low humidity air, resulting in solid particles containing two components, i.e., NaCl and fluorescein.

3) Local regions of high RH (> 80%) almost disappear near the boundary at large inhalation flow rates, e.g., 60 L/min; hence, hygroscopic growth of NaCl and fluorescein particles is suppressed.

4) The growth ratios of the deposited and escaped aerosols both decrease with increasing flow rates.

Understanding Particulate Matter Formation in CO2 Capture Plants using Molecular Dynamics Simulation. MEHDI AMOUEI TORKMAHALLEH, Mansurov Ulan, Dhawal Shah, *Chemical and Aerosol Research Team, Nazarbayev University*

Carbon capture has been proposed as a viable method that is capable to reduce CO2 emissions from power plants by 80 % to 90 %. The most advanced method in terms of industry is post-combustion CO2 capture (PCCC) using aqueous monoethanolamine (MEA) as a solvent. However, a major factor that precludes its widespread implementation is the high cost of the process, which is largely conditioned by substantial solvent losses during the process. These losses have been strongly linked to formation of aerosols or particulate matter (PM). Due to recent emergence of the issue, formation of aerosols (PM) has been an object of only few studies. Several efforts were made to model PM formation and behavior using commercial software such as ASPEN PLUS and MATLAB. Nevertheless, since these programs cannot model nucleation process, the attempts possess certain fundamental shortcomings. This original research aims to address the issue of PM formation in a PCCC absorption column at a molecular level using molecular dynamics simulation. The simulations were carried out using GROMACS software. Five different systems were considered including various configuration of components. Clustering effect of molecules has been observed in four systems out of five. Essentially, these molecular clusters are PM that emerge as a separate phase in the gas phase. Nucleation rate of the PM were in the order of 10-30 cm-3s-1 in all systems. In the systems with one condensable component PM formation was governed by saturation ratio. On the contrary, in the systems with several condensing components nucleation process was observed even if the gas phase was slightly sub-saturated. Special emphasize was made on interaction energies between participating components which drive the formation of PM. Inferred from simulation results, strong short-range attraction energy was reveled between water and CO2 and between water and MEA. Furthermore, radial distribution analyses were performed to examine the structure of formed PM. Based on the findings of the study certain practical suggestions were offered to decrease the formation rate of PM in a PCCC column.

6AM.7

Aerosol Formation and Growth in Amine-based CO2 Scrubber: Experiments and Numerical Simulation. DAVID I. A. DHANRAJ, Zhichao Li, Pratim Biswas, *Washington University in St. Louis*

The concerns owing to global warming and climate change have initiated significant efforts to reduce the concentration of atmospheric CO_2[1]. Post-combustion CO_2 capture using amine solvents is currently the key economical retrofit process for large power plants[2]. Amine loss is a primary challenge for amine-based CO_2 scrubbing technology considering its environmental and economic impacts. The presence of fine particles in flue gas is regarded as the major contributor of aerosolized amine emissions. Experiments using a lab-scale structured packing spray column were conducted to investigate the effects of inlet particle size distribution, gas flow rate and amine flow rate on the particle size distribution at the outlet. The results indicate that the total number concentration of particles with diameter in the range from 10 nm to 450 nm increased significantly after passing the scrubber. It was also seen that a small fraction of the particles larger than 1 µm was trapped in the scrubber. From these experiments, it can be inferred that increasing the number concentration of submicrometer particles and liquid flow rate could further increase the aerosol emission. Moreover, it is known that supersaturated amine in the vapor phase is the major contributor of aerosolized amine emissions. Amine vapor condenses on the fine particles and further grow by coagulation. In order to understand the processes that govern the formation and growth of particles, a discrete sectional model was used to simulate the relevant physical phenomena under industrially relevant operating conditions. Further experiments are performed to investigate the effects of amine and CO_2 concentration, operating temperature and pressure on aerosolization. These experiments and simulations provide insights for optimized design and operation strategy in order to minimize amine losses in a full-scale amine scrubber.

A Field Dependent and Orientation Dependent Mobility Calculator: The Next Generation of Electrical Mobility Calculations. Behram Kapadia, Tianyang Wu, CARLOS LARRIBA-ANDALUZ, *IUPUI*

The ability to predict the electrical mobility of a charged entity from a molecular model is becoming of increasing interest as high resolution mobility measurements are more readily available. Most aerosol generated nanoparticles (and molecular ions and nanoclusters) are not spherical and require more than just a particle size to understand them or separate them. This asphericity may also be sought for as it may provide the particle with unique transport, optical and physical properties. Therefore, the commonly employed mobility diameter, i.e. the equivalent spherical diameter based on mobility measurements, while important in particle characterization, it is an ill conditioned parameter when dealing with molecules, nanocluster or particles with strikingly different aspect ratios. As such, we previously developed a very efficient parallelized state of the art algorithm, IMoS, that calculates collision cross sections (CCS) and mobilities of ion, clusters and nanoparticles within the free molecular regime from all-atom structures or coarse grain models. The CCS is equivalent to the mobility diameter but establishes the possibility of alluding to shape and orientation. It also has the advantage, unlike electrical mobility, that is not dependent a priori on the reduced mass of the gas-ion pair. For these reasons, it is the parameter of choice in IMoS to compare different nanoparticles/clusters.

The existing proposed algorithms however have their limitations. Among a few of such limitations, one can name 1) the calculations always assume that all orientations are equally probable ,2) that the mobility is independent of the electric field employed (true for E/N<<0), 3) that all atoms/coarse grained structures are assumed fixed which requires accommodation and reemission laws to be assumed and 4) that the ion/nanocluster has no rotational speed when the momentum exchange occurs.

Here we propose a novel MD/MonteCarlo algorithm that calculates the ion/nanoparticle as if it were in a real gas and subject to an arbitrary field in three dimensions. The ion/nanoparticle can freely rotate and its orientation, angular velocity and drift velocity are a function of the gas/ion collisions, the reduced mass, the strength of the field, and the position of the charges within the ion. It is the effect of the collisions and the particle orientation together with the electric field which now establishes the equilibrium drift velocity, preferred orientation, if any, and angular velocity. This equilibrium drift velocity, together with non-linearized theory establishes the relation between the field and the mobility which in turn yields the true mobility of the ion. This algorithm will not only provide new insights into mobility calculations never produced before but will also provide a unique understanding in multiple applications which involve charging efficiency, instrument sensitivity, diffusion losses or even collisional heating. The algorithm is parallelized and provides results within a reasonable amount of time. The code may also be extended out of the free molecular regime and into the transition regime when certain considerations are taken into account.

One Year Comparison of SOA Markers Modelling and Measurements: Seasonality and Gas/Particle Partitioning Evaluation. GRAZIA MARIA LANZAFAME, Deepchandra Srivastava, Florian Couvidat, Olivier Favez, Bertrand Bessagnet, Alexandre Albinet, *INERIS*

Secondary Organic Aerosols (SOA) account for a significant part of particulate matter (PM). Simulating their formation and fate remains challenging, since to date, air quality models usually underestimated them. SOA formation processes include multistep heterogeneous mechanisms, and their parametrizations involve several variables such as kinetic data and physical properties not well known. A better assessment of the SOA composition notably requires the understanding of the thermodynamic equilibrium of SOA compounds between the phases involved. This is usually done using either, theoretical, or experimental data. However, the validation of the modelling parametrizations developed must be done by comparison between measurement and modeling data. In this work, various key molecules, well known as SOA markers, have been modeled, using CHIMERE air quality model, through detailed formation pathways including the calculation of their gas/particle partitioning. Modelled concentration values have been compared to measurements of biogenic, (e.g. pinonic acid, pinic acid and MBTCA: α-pinene oxidation by-products), and anthropogenic (e.g. DHOPA: toluene SOA marker) SOA markers, performed on both, gaseous and particulate phases. Mechanisms have been developed based on data obtained from the Master Chemical Mechanism (NCAS, Universities of Leeds and York) and the scientific literature. The gas/particle partitioning has been calculated by using saturated vapor pressure and Henry’s constant values through the thermodynamic model SOAP. The gas phase chemistry has been simulated using MELCHIOR2. Biogenic emissions have been computed with the MEGAN 2.1 algorithm. The comparison has been done with SOA marker measurements performed for a one year period (2015) at the SIRTA sampling site (25 km SW from Paris city center). Filters and PUF (polyurethane foam) samples were collected every third day (24 h sampling) and then analysed by GC-MS after derivatization using native standards. The capacity of the model to reproduce seasonal variations of concentrations and the gas/particle partitioning (influenced by several parameters such as humidity and temperature) was evaluated.

Modification of the Versatile Aerosol Concentration Enrichment Factor System (VACES) for Cloud Condensation Nuclei Concentrator Purposes. CARMEN DAMETO DE ESPAÑA, Anna Wonaschuetz, Gerhard Steiner, Harald Schuh, Constantinos Sioutas, Regina Hitzenberger, *University of Vienna*

The activation of atmospheric aerosol particles into cloud droplets is fundamental for cloud formation. Cloud condensation nuclei (CCN), a subset of the atmospheric aerosol, constitute one of the largest uncertainties in estimating global climate change. The ability of atmospheric aerosol particles to act as CCN depends on many factors, including particle size, chemical composition, and meteorological conditions. To enlarge the knowledge on CCN, it is essential to understand the factors leading to CCN activation. For this purpose, a versatile aerosol concentrator enrichment factor system (VACES; Kim et al., 2001a; Kim et al., 2001b) has been modified to select CCN at different supersaturations. VACES allows for sampling of CCN particles without altering their chemical and physical properties. The redesigned VACES enriches CCN particle concentrations by first passing the intake flow to the saturator and then to the condenser. The activated particles are concentrated by an inertial virtual impactor, and then returned to their original size by diffusion drying. For the calibration, the saturator temperature was fixed at 50°C and the condenser temperature range was varied from 0°C to 40°C to obtain the activation curves for the different particle sizes. Knowing the activation dimeter, it was possible to calculate the supersaturation. Calibration results have also shown that CCN concentrations can be enriched by a factor of approx. 16. This correlates to the theoretical results. The theoretical enrichment factor is represented by the inlet main flow divided by the outlet minor flow which are 100 lpm and 5 lpm respectively.

Method to Retrieve Cloud Condensation Nuclei Number Concentrations Using Multiwavelength Raman Lidar.

WANGSHU TAN, Chengcai Li, Yingli Yu, Chunsheng Zhao, *Peking University*

The uncertainties associated with the estimated climate forcing attributed to aerosol-cloud-interaction still span over a poorly constrained range. Determination of cloud condensation nuclei (CCN) number concentration (N_{CCN}) at cloud base is of central importance in aerosol-cloud-interaction observations. Ground-based lidar continuously provides useful vertical information about aerosols up to the cloud base and has potential to provide profiles of CCN-relevant particles. In this work, we propose a novel method to retrieve N_{CCN} by multiwavelength Raman lidar based on Mie theory and κ-Köhler theory using in situ aerosol measurement datasets. Variances of lidar-derived backscatter coefficient (β) and/or extinction coefficient (α) among different wavelengths, usually expressed as Ångström exponent, can describe the predominant size of aerosols. Enhancements of β and α with relative humidity in vertical direction are utilized to represent the hygroscopicity of aerosols. Results show that α contains more CCN-relevant information than β, and their enhancements with relative humidity are highly consistent with aerosol hygroscopicity. For a lower supersaturation ratio (0.1%), the retrieved error of our method is less than 20% only with β. For a higher supersaturation ratio (0.8%)， large systematic bias is found and the results significantly improve when α is adopted. We find that particles with diameters of 50-100nm dominate the retrieve bias at supersaturation ratio of 0.8%, because optical properties at lidar wavelengths are not sensitive to particles smaller than 100nm. This new method to retrieve N_{CCN} at cloud base directly from lidar observations would be able to provide long-term CCN data for aerosol-cloud-interaction studies.

CCN Activity of Secondary Organic Aerosol Largely Controlled by Molecular Weight. JIAN WANG, John Shilling, Jiumeng Liu, Alla Zelenyuk, David Bell, Markus Petters, Ryan Thalman, Fan Mei, Rahul Zaveri, Guangjie Zheng, *Brookhaven National Laboratory*

Aerosol particles strongly influence global climate by modifying the albedo and lifetime of clouds. An accurate assessment of the aerosol impact on climate requires the knowledge of the concentration of cloud condensation nuclei (CCN), a subset of aerosol particles that could activate and form cloud droplets in the atmosphere. Atmospheric particles often consist of hundreds, or even thousands of organic species, which collectively often dominate the composition of aerosol particles. As a result, CCN concentrations can be very sensitive to the hygroscopicity of the organics in the particles. Laboratory and field studies show organic hygroscopicity increases nearly linearly with the atomic O:C ratio (i.e., oxidation level). Such increase in hygroscopicity has long been thought a result of higher polarity and therefore increased water solubility for more oxygenated organics. In this study, we systematically characterized organic hygroscopicity of secondary organic aerosol (SOA) formed from representative precursors. We show that for the majority of SOA, organic hygroscopicity is mainly controlled by the molecular weight. Instead of increased water solubility, the increase of the organic hygroscopicity with O:C is to a large degree due to that (1) SOA formed from smaller VOC molecules tends to have lower molecular weight and higher O:C and (2) during oxidation, fragmentation produces organic molecules with lower molecular weight. A simple model of organic hygroscopicity based on molecular weight, O:C, and volatility is developed, and it successfully reproduces the variation of SOA κorg with O:C observed in the laboratory and field studies.

A Model Intercomparison of CCN-Limited Tenuous Clouds in the High Arctic. Robin Stevens, HAMISH GORDON, Katharina Loewe, Christopher Dearden, Antonios Dimitrelos, Anna Possner, Gesa Eirund, Tomi Raatikainen, Adrian Hill, Benjamin Shipway, Jonathan Wilkinson, Sami Romakkaniemi, Juha Tonttila, Ari Laaksonen, Hannele Korhonen, Paul Connolly, Ulrike Lohmann, Corinna Hoose, Annica Ekman, Ken Carslaw, Paul Field, *University of Leeds*

A decrease in Arctic sea ice extent and thickness has been observed within recent decades. Further decreases in Arctic sea ice extent are expected to increase the fluxes of aerosol and aerosol precursor gases as well as latent heat and sensible heat from the open ocean surface within the Arctic. Additionally, Arctic aerosol concentrations could be significantly impacted by changes in non-local aerosol sources and changes in the long-range transport of this aerosol, and increases in shipping traffic as the Arctic becomes seasonally ice-free. This increase in shipping traffic would also be expected to yield an increased demand for accurate weather forecasts over the Arctic region. However, it remains unclear whether the net effect of these changes in aerosol concentrations and surface fluxes would result in an increase or a decrease in cloud cover or drizzle precipitation. The changes in cloud properties could strongly influence the radiation budget in the Arctic, resulting in feedbacks on the rate of sea-ice loss. Arctic clouds remain poorly understood, and the current representation of these processes in global climate models is most likely insufficient to realistically simulate long-term changes.

In order to better understand the processes controlling Arctic clouds and their uncertainties in current models, we perform a model intercomparison of summertime high Arctic (> 80 N) clouds observed during the 2008 Arctic Summer Cloud Ocean Study (ASCOS) campaign, when observed cloud condensation nuclei (CCN) concentrations fell below 1 cm^{-3}. Previous analyses have suggested that at these low CCN concentrations the liquid water content (LWC) and radiative properties of the clouds are determined primarily by the CCN concentrations, conditions that have previously been referred to as the tenuous cloud regime. The intercomparison includes results from three large eddy simulation models (UCLALES-SALSA, COSMO-LES, and MIMICA) and three numerical weather prediction models (COSMO-NWP, WRF, and UM-CASIM).

We test the sensitivities of the model results to different treatments of cloud droplet activation, including prescribed cloud droplet number concentrations (CDNC) and diagnostic CCN activation based on either fixed aerosol concentrations or prognostic aerosol with in-cloud processing. We investigate the sensitivities of the model results to changes in these prescribed CDNC, fixed CCN, or prognostic CCN concentrations. Further, we examine the interaction of model sensitivity to CCN concentrations with changes in prescribed ice crystal number concentrations (ICNC). We also examine the interaction of model sensitivity to CCN concentrations with changes in surface heat and moisture fluxes due to a removal of sea-ice cover.

The results strongly support the hypothesis that the liquid water content of these clouds is CCN-limited. For the observed meteorological conditions, the cloud generally did not collapse when the CCN concentration was held constant at the relatively high CCN concentrations measured during the cloudy period, but the cloud thins or collapses as the CCN concentration is reduced. Our results also show that cooling of the sea-ice surface following cloud dissipation increases atmospheric stability near the surface, further suppressing cloud formation. This effect does not occur in simulations with a sea-ice-free surface.

There remains considerable diversity even in experiments with prescribed CDNCs and prescribed ICNCs. The sensitivity of mixed-phase Arctic cloud properties to changes in CDNC, and hence to changes in aerosol concentrations, depends on the representation of the cloud droplet size distribution within each model, which impacts on autoconversion rates. Our results therefore suggest that properly estimating aerosol–cloud interactions requires an appropriate treatment of the cloud droplet size distribution within models, as well as in-situ observations of hydrometeor size distributions to constrain them.

Marine Aerosol Cloud Activation. JURGITA OVADNEVAITE, Kirsten Fossum, Darius Ceburnis, Colin O'Dowd, *National University of Ireland Galway, Ireland*

Marine aerosol occurring in cloud condensation nucleus (CCN) sizes suggest that it may contribute notably to the CCN population, but further cloud droplet number concentration would strongly depend on the chemical aerosol composition and ambient (cloud) conditions, such as available water content, supersaturation and competition between the CCN of different composition (O'Dowd et al., 1999). Since the global importance of marine aerosol particles to the cloud formation postulated several decades ago, it has progressed from the evaluation of the nss-sulphate and sea salt effects to the acknowledgement of the significant role of organic aerosol (O'Dowd et al., 2004). It has been demonstrated that primary marine organics, despite its hydrophobic nature, can possess the high CCN activation efficiency, resulting in the efficient cloud formation (Ovadnevaite et al., 2011). Organic aerosol, ubiquitous in both clean and polluted atmosphere, can be present as a pure organic aerosol or and internally-mixed aerosol with other constituents such as sulphate and nitrate aerosol. The hygroscopicity of organic aerosol in sub-saturated humidity fields is typically less than most common salts found in the atmospheric aerosol; however, the ability of organic aerosol to activate cloud droplets is predicted to be greatly increased in supersaturated air due a lowering of the droplets surface tension, ultimately leading to more nuclei being activated at lower supersaturations (Facchini et al., 2000). While this phenomenon has been acknowledged for some time, we've demonstrated it in the real atmosphere (Ovadnevaite et al., 2017). Here we show the organic effect on primary and secondary marine aerosol activation to CCN. Results from two intensive measurement campaigns in the Eastern North Atlantic (Mace Head) and the Southern Ocean (PEGASO cruise) are presented here with the main focus on CCN dependence on aerosol chemical composition and, especially, origin and sources of marine organic. We investigate the activation of sea spray composed of the sea salt and externally mixed with nss-sulphate as well as the sea spray highly enriched in organics, stressing the importance of the latter to the formation of the cloud droplets. In addition, the organic effect on CCN activation of newly formed marine particles is investigated.

The Role of Aerosol-Radiative Forcing on the Monsoon Trough Oscillations. RAJA BORAGAPU, Padmakumari B., R.S. Maheskumar, *Indian Institute of Tropical Meteorology (IITM), Pune, India*

The monsoon trough (MT) which forms as an elongated low pressure system over the northwestern part of South Asia during monsoon is part of the northward shifted Inter Tropical Convergence zone (ITCZ). Changes in the strength of MT can affect land-sea thermal contrast and further affect the advancement (progression) of the monsoon circulation. Any shift in the normal MT position causes shifts in the synoptic rain-bearing systems such as depressions leading to reduced rainfall over one region and enhanced over the other. The position of MT plays a major role as its southward shift leads to active and whereas northwards to the foothills of Himalayas causing break spells. On the other hand, aerosols through its interaction with radiation can increase the atmospheric stability and weaken the strength of the trough. Recent studies have shown a drying of the northern hemisphere mainly due to the aerosol induced cooling causing a southward shift in the climatic position of the convergence zone which may directly affect the total monsoon precipitation over the core monsoon zone in Central India. Therefore, using both observational and modelling approach this work attempts to understand the role of aerosol-radiation interactions in the MT oscillations. In the present study the impact of aerosols on MT characteristics and the resultant changes in the total precipitation during active and break conditions are explored and will be presented.

6CC.7

Overview of Fog Water Chemistry in Namibia during the AEROCLO-sA Campaign. Denise Napolitano, Stéphanie Rrossignol, Chiara Giorio, Roland Mushi, Gillian Maggs-Kölling, Barbara D'Anna, Bruno Coulomb, Jean-Luc Boudenne, Stuart J. Piketh, Andreas Namwoonde, Paola Formenti, Anne Monod, PIERRE HERCKES, *Arizona State University*

Namibia is an arid country where many rural and urban centers depend on ephemeral rivers for their water supply. These water sources are, however, limited and display seasonal salinization. Fog occurs along the coast and extends for up to 100 km inland, and has been considered for a long time as a source of drinking water. Fog is also a vital source of moisture for the endemic flora and fauna of the Namib Desert. However, due to the current change in climate and air quality, fog occurrence and composition, of crucial importance for the local ecosystems and populations, may be impacted.

The AErosol RadiatiOn and CLOuds in southern Africa (AEROCLO-sA) project investigated the interactions between aerosols, clouds and radiation fog in the South East Atlantic off the western coast of southern Africa. Within this framework fog and aerosol samples were collected in Henties Bay (Namibia), right at the Atlantic Ocean during an intensive campaign in September 2017. Eight fog events were sampled with two Caltech Active Stand Cloud Water Collectors (CASCC) operated in parallel, one stainless steel collector for organic matter analysis and one plastic collector for inorganic species characterization.

Fog samples were analyzed for pH, major ions, trace metals and organic carbon content (TOC and DOC). In addition, the fog samples were characterized by aerosol mass spectrometry (AMS-c-TOF-MS) and by optical spectroscopy including UV-VIS and 3D fluorimetric analysis. The results of the study will be presented and discussed relative to chemical data on local seawater and aerosol samples. Sea spray has been identified as the major source of many chemical species in these fogs. These results will be contrasted with fog chemistry observations at a more inland site in Namibia at the Gobabeb Research and Training Center. Here the marine impact is less dominant for many species.

6CC.8

Coastal Aerosol and Fog Microphysics in Atlantic Canada. RACHEL CHANG, Patrick Duplessis, Sean Hartery, Sonja Bhatia, Michael Wheeler, Annie Marie Macdonald, *Dalhousie University*

Fog reduces visibility, causing delays in transportation by land, sea and air. It is also a safety hazard that results in accidents and sometimes even death. Like cloud droplets, fog droplets form on cloud condensation nuclei, existing aerosol particles in the atmosphere that have the ability to activate into droplets. As such, fog provides a unique, in situ method of studying the process of aerosol activation. The interactions between aerosols and water vapour can determine the formation and persistence of fog, which makes fog forecasting challenging. Current parameterizations suffer notably from unresolved microphysical problems such as neglecting droplet concentration, which leads to large errors in droplet density predictions and therefore visibility. This study presents results from a fog study conducted on the eastern coast of Canada in Nova Scotia during the early summer of 2016. Observations of aerosol size distributions and chemical composition were conducted behind a ground-based counter flow virtual impactor, allowing the droplet residuals to be measured directly. Fog droplet size distributions, visibility and other meteorological variables were also measured at the same time. Aerosol and droplet microphysical parameters will be presented including the influence of air mass history on visibility. Preliminary results show that aerosol growth may be contributing to the dissipation of fog under some conditions, suggesting that despite the importance of dynamics on fog formation and dissipation, aerosols can also play an important role in the life cycle of fog.

6CC.9

Single Particle Measurements of Size and Mixing State of Black Carbon Particles Combined with Simplified κ-Köhler Theory Explains Their Droplet Activation Behaviour Observed in Fog and Clouds. MARTIN GYSEL, Ghislain Motos, Julia Schmale, Joel Corbin, Marco Zanatta, Robin Modini, Urs Baltensperger, *Paul Scherrer Institute*

Black carbon (BC) is an aerosol component, mainly emitted from anthropogenic sources, with peculiar properties. BC is the major light-absorbing component of atmospheric aerosols due to its high mass absorption coefficient (MAC), therefore causing substantial climate warming through aerosol-radiation interactions (ARI). BC in pure form is a poor cloud condensation nuclei (CCN) due to its insolubility, which makes wet deposition through the droplet nucleation pathway inefficient. Freshly emitted BC is often externally mixed, while it tends to acquire coatings during atmospheric aging processes. Such coatings can increase the MAC of BC. However, the corresponding effect on ARI may be partly compensated by reduced BC burdens as a consequence of better CCN activity and thus more efficient wet removal. In this study we address the droplet activation of BC in ambient fog and clouds, and assess whether BC activation can be predicted from measured BC properties.

A first field experiment was conducted in Zurich, Switzerland, an urban site where fog regularly occurs and where a mixture of fresh and aged BC is encountered. A second field experiment was conducted at the Jungfraujoch, Switzerland, a high-alpine site frequently exposed to clouds and with highly aged free tropospheric aerosol. Aerosol was sampled during fog/cloud periods using a total inlet to collect the aerosol as a whole (interstitial plus droplet residual particles) and an interstitial inlet to exclusively collect interstitial particles. Aerosol size distribution (mobility particle size spectrometer) as well as BC core size distribution and mixing state (single particle soot photometer, SP2) were measured behind both inlets along with complementary measurements.

Comparison of the measurements behind these two inlets makes it possible to compare the properties of particles that activated to cloud droplets with those remaining interstitial. The size distribution data provide the activation cut-off diameter representative of BC-free particles, from which the fog/cloud peak supersaturation is inferred. The SP2 provides, within its detection limits, the volume equivalent total particle and BC core diameters of BC-containing particles. This information combined with coating hygroscopicity was used as input for κ-Köhler theory to infer the critical supersaturation for CCN activation of BC on a single particle basis. Validity of these predictions was tested by comparing predicted critical supersaturations measured for BC particles behind the two inlets for fog/clouds with known peak supersaturation.

The fog in Zurich was characterized by large activation cut-off diameters of BC-free particles, which implies very low peak supersaturation. The BC particle activation agreed with predictions both qualitatively and quantitatively: activated fraction increased with increasing coating thickness for a fixed core size, the coating thickness at 50% activation decreased with increasing core size, and the observed dependence of the activation cut-off on size and mixing state of BC matched the theoretical line for the peak supersaturation in the fog events. Similar agreement between prediction and measurements was also found for the clouds at Jungfraujoch, though with more limited “data coverage” as clearly higher peak supersaturations shift the activation cut-off diameters towards the lower limits of detection of the SP2.

In conclusion, we achieved successful closure between observed droplet activation of BC and predictions based on measured size and mixing state for a range of peak supersaturations. This shows that assuming spherical core-shell morphology, which is implicitly done in both SP2 data analysis and κ-Köhler theory, describes activation behavior of atmospheric BC in good approximation. This validates application of κ-Köhler theory based on droplet activation in model simulations in which BC size and mixing state is available on a mass or volume basis.

6CD.1

Lung Capacity of Traffic Wardens Affected by Vehicular Pollution in Lahore, Pakistan. SAIMA YAQUB SHELLY, Husna Malik, Zulfiqar Ali, Farkhanda Manzoor, Sammuel Shahzad, Zaheer Ahmad Nasir, *Lahore College for Women University, 54600, Lahore, Pakistan*

Lahore was selected as the study site as it being the heart of Punjab and also the second most densely populated city of Pakistan and the 42nd most populous city in the world with a population of about 11 million people with a 2% growth rate leading to high number of increase in motorized vehicles in the last decade as well as the city attracting a higher number of commuters. It was the first city where the Traffic warden system were employed for the first time. A total recruitment of 3300 wardens were piloted in the past ten years.These wardens are alternated between areas of high, moderate and low traffic but being exposed to heavy vehicular pollutants has lead to health deterioration on a large scale. Long standing stressful duty hours increases the tendency to lose health faster than the common man. This study was conducted on randomly selected traffic wardens to check if the lung capacity of these physically well looking individuals has deteriorated with the passage of time along with pollution episodes at peak and non-peak hours in all ten towns of Lahore in both summer and winter seasons.

The lung capacity was measured for 500 cases under study by a digital portable spirometer MDX Spiro Tron. The values of FVC, FEV1 FEV1 predicted and FEV1/FVC were then used to categorize the individuals as per standards followed for Asians by National Institute for Health and Clinical Excellence (NICE) 2010 for severity of Chronic Obstructive Pulmonary Disease (COPD). Vehicular pollution data was monitored on ten sites marked throughout Lahore for sixteen hours each in both winters and summers for Temperature, Humidity, Nitrogen Dioxide (NO2), Carbon Monooxide (CO), $PM_{2.5}$ and PM_{10} with the help of Aeroquel portable monitor 500 for gases and GRADKO DC 1700 for particulate matter. The traffic density on the selected points was calculated by the number of vehicles crossing in a 24 hour time period, thus dividing the areas into Light, moderate and Heavy traffic density zones. The data obtained from the monitors was statistically analyzed by SPSS and reported.

The environmental data was collected during the summer and winter season for sixteen hours each with an interval of fifteen minutes. The data for wind speed and direction was obtained from the metrology department and depicted by synoptic charts denoting the level of pollution at the particular area when it was monitored.

It was observed that the temperature varied non-significantly between the towns whereas the humidity, CO level, NO_2 level, $PM_{2.5}$ and PM_{10} varied significantly between the towns. Significant correlation was observed between the varying seasons and temperature and $PM_{2.5}$ whereas as the humidity, CO and NO_2 correlated negatively with the seasonal changes. Temperature showed negative correlation with humidity and CO whereas NO_2 showed negative correlation with particulate matter value. Significant difference was observed for $PM_{2.5}$, PM_{10} and CO among towns with light and heavy traffic in both the summer and winter seasons.

As per the Kruskal-Wallis test the values of FEV1 and FEV1Pred also varied significantly for wardens of different towns in Lahore. Strong positive correlation was observed with high traffic density and low FVC and FEV1 values.

It is thus concluded from the study that the areas containing heavier load of traffic are more prone to emission to gases coming from those vehicles causing lung damage showed by decreased values of FEV1 and FEV1 predicted in individuals who have worked for longer periods of time and have been exposed the most thus concluding that long term exposure of vehicular emissions leads to lower lung capacities and higher disease symptoms.

6CD.2

Characterization of Electrophilic and Oxidative Potential of Atmospheric Carbonyls. JIN CHEN, Stacy Chen, Cody Cullen, C.M. Sabbir Ahmed, Ying-Hsuan Lin, *University of California, Riverside*

Ambient particulate matter (PM) is a prominent environmental risk factor associated with adverse human health effects such as asthma, cancer, and chronic obstructive pulmonary disease. PM represents a complex mixture consisting of numerous individual compounds, including carbonyls, which play a crucial role in atmospheric oxidation processes. Owing to the complex nature of atmospheric PM, currently a comprehensive understanding of molecular composition and toxicity of individual aerosol components is lacking. Sources of atmospheric carbonyls include direct emissions from cooking, cigarette smoke, and fuel combustion, or they can be generated through atmospheric degradation of volatile organic compound precursors. Upon exposure, some carbonyls such as unsaturated aldehydes are strong electrophiles that can react with thiol antioxidants and protein residues to induce inflammation and cellular oxidative stress. In this study, we calculate the global electrophilicity of atmospherically relevant carbonyls with computational chemistry approaches to estimate their chemical reactivity. Dithiothreitol (DTT) activity, a commonly used measure for PM oxidative potential, is assessed as a surrogate of biological activity. The reaction products of carbonyls with DTT are characterized using gas and liquid chromatography-mass spectrometry based methods to understand reaction pathways. The potential of using global electrophilicity as a descriptor for carbonyl reactivity in PM and toxicity screening will be discussed.

6CD.3: INVITED

Connecting the Dots in Nanotoxicology: From the Bio-Nano-Interface to Adverse Health Effects. Stefano Poggio, David Power, Hender Lopez, VLADIMIR LOBASKIN, *School of Physics, University College Dublin*

A definitive conclusion about the dangers associated with human or animal exposure to a particular airborne nanomaterial (NM) can currently be made upon complex and costly procedures including complete NM characterization with consequent careful and well-controlled in vivo experiments. A significant progress in the ability of the robust nanotoxicity prediction can be achieved using modern approaches based on the one hand on systems biology and on the other hand on statistical and other computational methods of analysis. Without the mechanistic understanding of the toxicity, one can only rely on statistical correlations between the NM properties and the toxicity endpoints. Thanks to the development of systemic approaches to analysis of biological systems (systems biology) and new methods of characterization and data generation in toxicology in the recent years, we are now in a position to make a step forward from the black-box-type statistical approaches and formulate a new paradigm in the toxicology – a mechanism-aware NM toxicity screening. We contend that the game-changing screening approach should be based on the detailed understanding of the response of the organism to exposure to NMs from the initial contact to the adverse outcome. To recover the mechanistic picture, we developed a research programme which includes in-vivo, in-vitro and in-silico studies to address main respiratory toxicity pathways, identify the mechanistic key events of the pathways, and relate them to interactions at bionano interface via careful post-uptake NM characterisation and molecular modelling, which is now funded through EU H2020 SmartNanoTox project.

In the SmartNanoTox project, we propose to construct a predictive model for gauging the toxicological and biological impacts of NMs using

- in vivo toxicity pathways for NMs that are of regulatory importance
- molecular initiating events and key events steering the toxicity pathways finally leading to an adverse outcome
- molecular mechanisms of NM involvement in these KEs
- structure and content of NM-biomolecule complexes after NM uptake.

The key step in the development of the smart screening approach is to combine the systems biology analysis of the responses of organisms to the NM exposure, resulting in a clear identification of the resulting pathways and key events, with the analysis of the whole chain of bionano interactions involving the NM inside the organisms.

The project team developed a number of innovative solutions to elucidate the key interactions involving airborn NMs. In this talk, I will present the project ideology and results to date.

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No. 686098.

The Impacts of Dust Storm Particles on Human Lung Cells - an Analysis at the Single Cell Level. KARIN ARDON-DRYER, Caroline Mock, Jose Reyes, Galit Lahav, *Department of Geosciences, Texas Tech University, Lubbock, T*

Aerosols particles (Natural and anthropogenic) are a key component of our atmosphere, their presence defines air quality levels and they can affect our health. Small particles penetrate into our lungs and this exposure can cause our lung cells to stress and in some cases leads to the death of the cells and to inflammation. During dust storm events there is an increase in particle concentration, many of them are breathable particles that can penetrate deep into our lungs. Exposure to dust particles can lead to respiratory problems, particularly for people with asthma. Therefore, during and after a dust storm event the number of people who are hospitalized with inflammation and respiratory problems increase. However, the exact mechanism that causes these health problems is still unclear. In this project, we are investigating the impacts that dust storm particles from different sources and of different concentrations (doses) have on human lung cells, performing a new and unique analysis at the single cell level. To accomplish this, each individual lung cell is continuously tracked after being exposed to dust particles. We monitor the behavior of the cell over time, identify the cells time of death and type of death (e.g. cell explosion). With this analysis, we can quantify cell death as a function of dust concertation (doses); to our surprise, an increase in cells death was not observed only as a function of an increase of dust concertation. In addition, we noticed that the way particles come in contact with cells, by sticking to or being engulfed by, and the interaction duration has an effect; cells that interact with dust particles for a longer period died earlier compared to cells with a shorter interaction period. These findings will help us to better understand the health-related consequences of exposure to dust storm events and serve as a baseline for when evaluating other aerosols.

Measuring the Real-Time Oxidative Potential of Ambient Particulate Matter Using an Online Mist Chamber System.

JOSEPH PUTHUSSERY, Chen Zhang, Vishal Verma, *University of Illinois Urbana-Champaign*

The oxidative potential (OP) of ambient particulate matter (PM) has been shown to be associated with various adverse health effects. Although there exist automated instruments which can measure the OP of ambient particles collected onto filters, there are both positive and negative artifacts associated with conventional filter sampling and their storage. Therefore, reactive oxygen species (ROS) activity measured on the archived filters is not representative of the real potential of ambient particles to generate ROS in the biological system on inhalation. To address this issue, we developed an automated online mist chamber (OMC) system to measure the hourly averaged OP of ambient PM using dithiothreitol (DTT) assay and tested it in the actual field conditions for over 50 days. The ambient particles were collected inside the mist chamber, and OP of the PM suspension was quantified using an automated instrument based on the DTT assay. The results from the online system correlated well ($R^2 > 0.80$) with conventional filter extraction method using both deionized water and methanol. The diurnal trend in the ambient particle OP during weekdays, measured by the online system showed a bi-modal trend with a peak during the morning period, followed by a broad peak (extending from 1 PM to 7 PM, but with a slight dip at 4 PM) during afternoon and early evening periods. We also conducted chemical speciation of the collected PM to link the diurnal variations in the concentrations of the redox active components (i.e., water soluble transition metals, organic carbon, water-soluble organic carbon, and elemental carbon) with the DTT activity. Based on our results, water-soluble Cu from non-exhaust emissions appear to be the major driver of the PM-induced OP during the daytime. Additionally, the secondary particles generated by the photochemical transformation of primary emissions were found to enhance the OP during the afternoon and evening periods. Future work in this direction aims to couple the OMC system to a comprehensive OP measuring instrument, which can measure both DTT consumption rate and hydroxyl radical (•OH) generation capability of aerosol particles using multiple assays (such as DTT assay and surrogate lung fluid assay).

Real-time Dosimetry for In-vitro Toxicological Studies of Engineered Nanoparticles (ENPs) at the Air-liquid Interface Using a Quartz Crystal Microbalance (QCM). Yaobo Ding, Patrick Weindl, Clara Wimmer, Paula Mayer, Tobias Krebs, OTMAR SCHMID, *Helmholtz Zentrum München, Germany*

Inhalation of engineered nanoparticles (ENPs), despite their unique physico-chemical properties compared to conventional materials, has been found to bear potential adverse effects on human health. In inhalation toxicology studies, direct air-to-cell exposure of ENP aerosols as possible with air-liquid interface (ALI) cell cultures provides a more physiologically-relevant platform to investigate their toxic effects, as compared to the traditional submerged cell culture systems. Moreover, the submerged cell exposures suffer from inaccurate control of the cell-delivered dose, which can be resolved by incorporating real-time dose measurement devices in ALI exposure systems.

In this study, we characterized the performances of the VITROCELL® CLOUD system (6- & 12-well model; VITROCELL Systems, Germany) for aerosolized ENP delivery to cells as well as the integrated QCM for measurement of the cell-delivered ENP dose. The system is equipped with a vibrating membrane nebulizer (Aeroneb Pro, Aerogen, Ireland) which generates aerosol droplets from a liquid suspension containing ENPs. As described by Lenz et al (2014) in the VITROCELL CLOUD system the aerosol droplets form a dense cloud, which utilizes cloud dynamics to rapidly (within 3 min) fill the exposure chamber, to uniformly mix the aerosol by vortex formation and to finally sediment the ENPs spatially uniform onto the transwell inserts containing the cells. A QCM is incorporated to monitor the cell-deposited dose.

A fluorescein solution was nebulized to investigate the uniformity and efficiency of aerosol deposition onto the cells cultured in transwell inserts as well as on the QCM. For the CLOUD 6 the deposition efficiency was 70.3%±1.9% and 63.5%±4.4% for inserts and the QCM, respectively, indicating no statistically significant difference. This was also the case for the CLOUD 12, but with slightly higher deposition efficiency (76-81%). These values are only weakly depended on the type of Aeroneb mesh nebulizers used. Out of six different nebulizers with varied output rates and droplet sizes, five resulted in the same deposition efficiency. Insert-to-insert variability was 4.4% and 6.0% for CLOUD 6 and CLOUD 12, respectively, within the range of nebulized volumes of ENP suspensions (50-400 µl). The QCM accuracy was 3.4% and 3.8% for CLOUD 6 and 12, respectively, as determined by using quantitative fluorescence spectroscopy on fluorescein as reference dosimetry method. The lower detection limit of the QCM was 500 and 170 ng/cm^2 for CLOUD 6 and CLOUD 12, respectively, which is above the onset dose for most types of ENPs. Finally, human lung epithelial cells (A549) were exposed to ZnO (JRC-NM110) nanoparticle aerosols and a dose-response relation was established from toxicological endpoints including cell viability (IC_{50}=ca. 0.5 cm^2/cm^2=4.2 µg/cm^2, membrane integrity and pro-inflammatory level.

Our results show that the VITROCELL-CLOUD systems can be used to deliver high dose rates of aerosolized ENPs (<1000 ng/cm^2/min) uniformly (<6% insert-insert variability) and efficiently to cells cultured at the air-liquid interface. Dose-response relationships can be readily determined with an integrated QCM providing real-time information on the cell-delivered ENP dose.

6CD.7

Application of Air-Liquid-Interface (ALI) Based In-Vitro Exposure of Human or Murine Lung Cells and Validation by Selected Animal Exposure Tests in the Framework of the HICE Consortium to Investigate Fresh and Aged Combustion Aerosols. RALF ZIMMERMANN, Maija-Riitta Hirvonen, Jorma Jokiniemi, Gunnar Dittmar, Jeroen Buters, Hanns Rudolf Paur, Carsten Weiß, Bert Buchholz, Tamara Kanashova, Sebastian Oeder, Marco Dilger, Tobias Krebs, Sven Ehlert, Thorsten Streibel, Juergen Schnelle-Kreis, Martin Sklorz, Stefanie Kasurinen, Sebastiano di Bucchianico, Johannes Passig, Jürgen Orasche, Mikko Happo, Hendryk Czech, Olli Sippula, Pasi Jalava, and further HICE co-workers (et al.), *Helmholtz Zentrum München and Rostock University*

Combustion aerosol emissions are responsible for acute and chronic health effects such as asthma exacerbation, heart-arrhythmia and heart-failure, lung cancer or COPD in humans. However, different combustion sources may have different health outcomes. Furthermore the effects may depend on the type of combustion compliance and can be mitigated/altered by abatement technologies. However, up to now only few links between aerosol chemical composition and biological effects have been established. Thus the relative toxicity of different combustion emissions needs to be determined experimentally. In the framework of the Virtual Helmholtz Institute-HICE (www.hice-vi.eu), physical and chemical properties of combustion emissions and their biological effects on lung cells (human epithelial cells: A549, BEAS2B and RAW/THP1 murine/human macrophages) are comprehensively analysed. For addressing the biological activity and toxicity of the aerosols, the lung cell-cultures were realistically exposed at the air-liquid interface (ALI) using 2 novel mobile automated ALI exposure-systems with 24 or 18 places for inserts with ca. 600.000 lung cells each (Vitrocell GmbH, Germany). The ALI systems are placed a mobile S2-bio safety laboratory (HICE MobiLab). One of the automated ALI systems is equipped with a newly developed exposure analysis system where the deposited mass, the particle size distribution (Topas GmbH, Germany) and the chemical composition is measured by mass spectrometry (Photonion GmbH). The cells are exposed with different moisturized com-bustion aerosols or clean air (reference). After 4h exposure biological effects were ana-lysed by multi-omics characterisation (transcriptomic, proteomic and metabolomics level) or assays for specific endpoints (viability, genotoxicity, cell integrity etc.). During all biological tests, the chemical composition and physical parameters of the emissions were thoroughly characterized (gases and particles). The acquired biological effects were comprehensively characterized and are put in context with the chemical and physical aerosol data (see e.g. Oeder et al., PLoSone 2015). For validation partly also animals (BL6 mice) are exposed in parallel to the ALI-exposures (RAW cells) and the macrophages from the broncheoalveolar lavage fluid (BALF) are subjected to molecular biological effects anaylsis as well. A first comparison of the effects from mice BALF (in-vivo) and RAW (in-vitro) for exposures with diluted exhaust from a Kubota diesel engine showed that immune response pathways are activated in both cases (in-vivo and in-vitro). Emissions from wood combustion (mansory heater, pellet burner and log wood stove, ship engines (heavy and light fuel oil), car engines (diesel, gasoline and ethanol fuels) were investigated by the ALI approach. Very recently lignite combustion and aging of wood and lignite aerosol emissions were investigated. The UV-light induced aging of the emission was performed in specially developed, high-throughput flow tube. In summary/conclusion observed biological response-strengths differ considerably for different combustion aerosol sources and are not well correlated to the deposited PM2.5-mass (i.e. partly also strong gas phase effects). This is suggesting large differences in the relative toxicity of the aerosol emissions from different combustion sources and fuel types. The aging experiments induce increased cytotoxicity, an effect which is currently deeper analyzed on the molecular biological level. In addition to adverse reactions also supposedly protective effects are observed. For example, the emission from a log-wood stove, exhibiting very high emission of soot, organics, PM2.5 are inducing only relatively mild acute effects in the ALI exposed cells, if compared to diesel or pellet burner emission. The high abundance of antioxidant compounds such polyphenols in the logwood stove-emissions may explain this counter-intuitive observation (Kanashova et al, J. Molec. Clin. Med., 2018). The latter findings are supported by detailed analyses of activated cellular response pathways (GO-term analysis), depicting regulation of pathways such as pro-inflammatory signaling, xenobiotic metabolism, phagocytosis or oxidative stress and findings from the selected animal exposure experiments.

6CD.8

Detection of Living Animal's Exhaled Breath Biomarker (dLABer) System. Haoxuan Chen, Xiangyu Zhang, Xinyue Li, Jing Li, MAOSHENG YAO, *Peking University*

In the past, toxicology studies are most offline, thus being not able to track the in situ responses of animals or humans to airborne pollutant exposure. Here, we report a system called dLABer that allows us to real-time monitor the breath-borne biomarkers. The system integrates living animals or humans, breath sampling, microfluidics, and biosensor. To test the dLABer, rats injected with PM were used as the subjects in this work. Our data showed that the dLABer were able to report IL-6 after 60 minutes from the breath sampling and can distinguish the different health effects caused by PM collected from different global cities based on the breath-borne IL-6 level. The results from the dLABer system were further validated using the ELISA for the air samples collected. In addition, the results from blood samples from the rats injected with different PM samples (the same mass) and also the DTT results agreed well with those from the dLABer system for breath-borne biomarker. In addition, video recordings also showed that rats exposed to PM with higher toxicity appeared to be less active, which was in line with the dLABer results. All the data (breath-borne, blood sera and DTT) suggested that the dLABer system can be used to real-time monitor breath-borne biomarkers. Results showed that the the dLABer were more sensitive than the traditional method ELISA, while the quantitative analysis capability of dLABer needs to be further improved. Here, we only tested the system for detecting biomarkers resulting from PM exposure, and in the future the dLABer system can be also used to detect the biomarkers resulting from the use of medications. Also, the system can be immediately used to monitor breath-borne biomarkers from humans in various scenarios. This work leads to a frontier method that is expected to revolutionize the pollutant health effects studies as well as many breath-borne disease diagnosis and studies.

6CD.9

Near-Roadway Effects on Expression of Autism Spectrum Disorder-Related Phenotypes. KEITH BEIN, Christopher Wallis, Xiao-San Luo, Elizabeth Berg, Michael Pride, Kelley Patten, Anthony Valenzuela, Eduardo Gonzalez, Jill Silverman, Pamela Lein, Anthony S. Wexler, *University of California Davis*

Recent epidemiological studies have linked traffic-related air pollution (TRAP) to increased risk of adverse neurodevelopmental outcomes, including psychomotor deficits, cognitive impairments, and autism spectrum disorders (ASD). In addition, in vivo and in vitro studies have shown that individual components of TRAP can alter neuroinflammation, alter neurotransmitter levels, and increase neurogenesis. However, TRAP exposures are challenging to reproduce in laboratory settings, and the mechanisms by which TRAP modulates neurodevelopment remain unclear. To address these issues, we exposed male and female Sprague-Dawley rats to real-time TRAP, using an exposure facility that samples air directly from a highway tunnel in the Bay Area of California used by both light- and heavy-duty vehicles. TRAP and filtered air (FA) PM samples were collected for 24 hours once every third day, and a subset of these were analyzed for particulate matter mass, organic and elemental carbon composition, and elemental composition. Gas phase samples were collected monthly on sorbents and analyzed for molecular organics. Rats were exposed to TRAP or filtered air (FA) from gestational day 15 to postnatal day 50. Following exposure, animals were assessed for ASD-relevant behavioral phenotypes and markers of brain cell development. The latter included microglial infiltration, reactive astrogliosis, and neurogenesis as assessed using immunohistochemistry, and ventricular volume and extra-cerebral volume as determined using magnetic resonance imaging (MRI). These data suggest that exposure of the developing brain to TRAP disrupts normal neurodevelopment.

This work was supported by the NIEHS (grants R21 ES025570 and P30 ES023513), NIA (grant P30AG010129), NICHD (grant U54 HD079125) and NIMH (T32 MH112507).

6IB.1: KEYNOTE
Mechanistic Modeling of Pathogen Transmission. LYDIA BOUROUIBA, *Massachusetts Institute of Technology*

The mechanisms governing the transfer of pathogens between infected and non-infected members of a population are critical in shaping the outcome of an epidemic. Despite major efforts aimed at the mathematical modeling and mitigation of infectious diseases, the fundamental mechanisms of pathogen spreading for most infectious diseases remain poorly understood. Drawing upon clinical or field data, fluid experiments and multi-scale mathematical modeling I will discuss the dynamics of transmission of various pathogens through the lens of fundamental fluid fragmentation.

6IB.3

Aerosol Particle Emission and Super-emission during Human Speech. SIMA ASADI, Anthony S. Wexler, Christopher Cappa, Nicole M. Bouvier, Santiago Barreda, William D. Ristenpart, *University of California Davis*

The traditional emphasis for airborne disease transmission has been on coughing and sneezing, which are dramatic expiratory events that yield easily visible droplets. Nonetheless, it has long been known that normal speech also yields expiratory aerosol particles. Recent research indicates that, compared to coughing, speech can actually release even larger quantities of such particles that are too small to see by eye, but are large enough to carry a variety of communicable respiratory pathogens. Here we show that the rate of aerosol particle emission during normal human speech is strongly correlated with the loudness (amplitude) of vocalization, ranging from approximately 1 particle per second for soft speech to over 50 particles per second at high amplitudes, regardless of the language spoken (English, Spanish, Mandarin, or Arabic). Furthermore, a small fraction of individuals behave as “superemitters,” consistently releasing an order of magnitude more aerosol particles than their peers. The results suggest that individual speech patterns could affect the probability of airborne respiratory disease transmission, and also help explain the existence of “superspreaders” who are disproportionately responsible for outbreaks of airborne infectious disease.

6IB.4

Novel Method for Identification of Airborne Transmission Using Molecular Epidemiology. Donald Milton, Daniel J. Nasko, TODD TREANGEN, *University of Maryland*

We subjected three pairs of fine-aerosol and NP swab samples (from our archive of 188 paired samples with detectable viral RNA in aerosol samples) to deep sequencing as described below (except that for exploratory analysis we used 20 samples per MiSeq lane). This preliminary sequencing effort tested the feasibility of the proposed work by selecting aerosol samples covering the range of measured fine-aerosol viral RNA content from ~10^3 to 10^7 copies per 1 mL. We achieved an average read depth of 15,000X per sample (ranging from 12,000X to 20,000X). All variants with p-value < 0.05 and at allele frequency >=2% were considered true variants; the rest were discarded as putative false positives. This cutoff level is consistent with those used in several recent analyses of the transmission bottleneck for influenza and high enough to exclude variants that would be unlikely to be transmitted through a bottleneck of 100. For each of the six samples sequenced for the feasibility study (three pairs of NP swab and aerosol), we identified the set of single nucleotide polymorphisms (SNPs) unique to one sample compared across all samples, unique to each member of the pair within the pair. The number of variants found in one but not both members of each pair ranged from 20 to 147 with no shared variants; thus, Jaccard similarity coefficients were zero. Phylogenetic analysis demonstrated that two of the paired samples were very closely related with consensus sequences differing by fewer than 10 SNPs. The third subject's consensus sequences from two sites differed by 73 SNPs, raising a question of two separate infection events at different sites. Overall, these preliminary data show that we can detect and distinguish variants and consensus sequences from the NP swab and the fine particle aerosol samples. If these results are confirmed by sequencing of additional samples, we will be able to establish that viral populations in the NP swabs and aerosol samples are independent. Success with these few samples suggests that we will be able to use the differences in consensus sequence and variant populations as markers of whether transmitted virus between two cases was from viral aerosol or a nasal source.

6IB.5

Foot-and-Mouth Disease Aerosols: Past and Future Perspectives. CLAIRE COLENUTT, Noel Nelson, Emma Brown, Simon Gubbins, *The Pirbright Institute*

Foot-and-mouth disease virus (FMDV) is a globally important pathogen of cloven hooved animals, which can be transmitted via numerous routes. Transmission through direct contact with infected animals is the most common route of spread of FMDV, but can be prevented by implementation of control measures, such as culling and movement restrictions. The role of indirect contact and fomite transmission is less well understood and more complex to apply effective control measures.

The ability of the FMDV to be transported long distances in aerosols given appropriate epidemiological and meteorological conditions has generated interest in understanding how the virus behaves in aerosol form and how this impacts on the overall epidemiology of the disease. Using empirical data generated in experiments, airborne spread of the virus can be modelled, alongside other transmission routes, to inform surveillance efforts and control measures in the event of an outbreak.

Here, we present a summary of research into FMDV aerosols. This covers work ranging from determining patterns of excretion of airborne virus from key susceptible livestock species, to demonstrating FMDV aerosols as a viable route of transmission. Numerous air sampling devices have been trialled for use in FMDV research, although the ideal qualities of equipment vary as to the research question being approached.

Existing research has provided answers to fundamental questions, but new tools and approaches are now required to be able to probe deeper into the aerobiology of FMDV. The development of operational tools to aid surveillance efforts in the event of an outbreak is a particular goal for future work. Research into FMDV aerosols is complicated by the need to carry out all experimental work under high containment. Ideal research methods and tools would incorporate the necessary protocols for containment and rigorous disinfection of equipment.

6IB.6

Stability of Variant H1 Subtype Influenza Viruses in Aged Aerosols and Their Infectivity in the Ferret Model. JOANNA PULIT-PENALOZA, Jessica Belser, Terrence Tumpey, Taronna Maines, *Centers for Disease Control and Prevention*

The relative importance of influenza virus transmission via aerosol inhalation is not fully understood and the subject of some debate. Detection of influenza virus RNA in the air collected directly from infected individuals and from contaminated spaces occupied by infected individuals, as well as mathematical modeling studies, suggest that aerosol transmission may represent a critical mode of seasonal influenza virus transmission in humans. Prototypical lab influenza viruses were shown decades ago to maintain viability in aerosols; however, there is a paucity of data available on currently circulating influenza viruses that significantly differ genetically and antigenically from their predecessors. In this study, we modified a previously established aerosol exposure system to assess stability in aerosols of four swine-origin variant H1 influenza viruses, isolated from humans in recent years, and a human seasonal influenza virus. Following nebulization of influenza virus into the primary exposure chamber, airflow through the chamber was interrupted to allow aerosol particles to age under still air conditions at 23-24°C and 45-55% relative humidity. Time-dependent loss of infectious virus was observed as evidenced by higher total viral RNA levels over total viable virus. Among the H1 viruses tested here, stability in aerosols correlated with transmissibility between ferrets, the gold standard animal model of influenza infections in humans. The influenza viruses that were transmissible through the air with 100% efficiency among ferrets displayed higher stability in aerosols than the viruses that transmitted with lower efficiency. Virus-laden aerosols aged for 15 or 30 min were able to productively infect ferrets at low doses, despite diminished viral viability compared with aerosols that were generated immediately prior to ferret exposure. Collectively, these data underscore the high infectivity of influenza viruses in aerosols, and support the need for continued refinement and innovation of laboratory methods to investigate mammalian exposure to inhaled pathogens. The results of this study further our understanding of the public health threat posed by novel influenza viruses as they continue to cross the species barrier to cause human infections.

6IB.7

Influenza Virus Maintains Infectivity in Droplets and Aerosols Independent of Relative Humidity. Karen Kormuth, Kaisen Lin, Aaron Prussin II, Eric Vejerano, Andrea Tiwari, Steve Cox, Mike Myerburg, Seema Lakdawala, LINSEY MARR, *Virginia Tech*

Previous studies have suggested that humidity contributes to the seasonality of influenza because the virus appears to survive better in droplets and aerosols under cold, dry conditions. However, there are conflicting findings about virus viability across the full range of relative humidities (RHs). Our objective is to determine the relationship between RH and influenza virus viability in droplets and aerosols of physiologically realistic composition. We exposed a circulating strain of influenza virus (2009 pandemic H1N1) in both stationary droplets and suspended aerosols to RHs ranging from 23% to 98%. The virus was prepared in a 1:10 mixture of human bronchial epithelial extracellular material and L-15 media. Over the 1-hour exposure period, the virus did not lose infectivity at any of the RHs tested. Our data suggest, for the first time, that influenza viruses remain highly stable and infectious in aerosols, independent of RH. When the extracellular material was heat-treated to denature proteins, the virus did not survive as well, particularly at RHs around 50%, as seen in prior studies. A parallel experiment with the enveloped bacteriophage Phi6 showed that the human bronchial epithelial extracellular matrix conferred a protective effect on this virus, too, and confirmed that viability in stationary droplets was similar to that in suspended aerosols. These results have significant implications for understanding the mechanisms of transmission of influenza and its seasonality.

6IB.8

Aerosol and Surface Sampling for a Novel H7N2 Influenza A Virus at a New York City Feline Quarantine Facility.

WILLIAM LINDSLEY, Francoise Blachere, Angela M. Weber, Donald Beezhold, Robert Thewlis, Kenneth R. Mead, John Noti, *National Institute for Occupational Safety and Health*

Influenza is of tremendous concern to the public health community because of the potential for new strains of the virus to cause a severe pandemic. In December 2016, an outbreak of a novel avian-lineage H7N2 influenza A virus was detected among cats in three animal shelters in New York City. H7N2 influenza had never been previously reported in cats, and further investigation found that at least one case of cat-to-human transmission to a veterinary staff member had occurred. To contain the outbreak, 500 cats that were potentially exposed to the virus were moved to a temporary feline quarantine facility and infection control measures were implemented.

In order to better understand the possible transmission pathways of the virus and the occupational exposure risk for animal shelter workers, the National Institute for Occupational Safety and Health (NIOSH) conducted aerosol and surface sampling in the quarantine facility. The quarantine facility was housed in a two-story warehouse with recirculating air heaters and natural ventilation. The animal isolation zone had a floor area of approximately 220 m2 (7800 ft2) and a ceiling height of approximately 3.7 m (12 feet). During sampling, the interior temperature was 18°C and the relative humidity was 25%.

Twenty aerosol samples were collected using NIOSH two-stage cyclone aerosol samplers with a 3.5 liter/min sampling rate for 4-5 hours. The NIOSH sampler separates aerosol particles into three size fractions (≥4 µm, 1 to 4 µm, and ≤1 µm) and conforms to the ACGIH/ISO criteria for respirable particle sampling. Sixteen aerosol samples were collected within the isolation zone, and all of these samples were positive for the H7N2 virus by RT-PCR. The mean concentration of airborne H7N2 influenza virus was 5810 viral copies/m3 of air (SD 4230). Seventy-one percent of the virus was detected in particles ≥4 µm, while 28% was found in 1-4 µm particles, and 1.4% in ≤1 µm particles. Influenza was not detected in 4 aerosol samples collected outside the isolation zone.

Thirteen aerosol samples were collected in the isolation zone using SKC BioSamplers at 12.5 liters/minute for 60 minutes. The SKC BioSampler collects particles into a liquid viral transport media, which helps preserve the viability of the virus. Sterile distilled water was added to the BioSamplers every 15 minutes as needed to replace water lost due to evaporation. Twelve of these aerosol samples were positive for H7N2 influenza by RT-PCR, with a mean airborne concentration of 3260 viral copies/m3 of air (SD 1830). Viable airborne influenza virus was detected in 6 samples.

Thirty-one surface samples were collected using sterile nylon-flocked swabs moistened with viral transport media. Of the 22 surface swabs taken in the isolation zone, 17 were positive for H7N2 influenza by RT-PCR, with a mean of 1030 viral copies/sample (SD 1890). Viable influenza virus was detected in 5 surface samples. Nine surface swabs were collected outside of the isolation zone, none of which were positive for influenza.

The results of this study show that airborne and surface H7N2 influenza virus were pervasive throughout the isolation zone of the quarantine facility, which suggests that airborne, droplet and contact transmission were all potential pathways for the spread of the virus. These results also indicate that occupational exposures to the virus could occur by all three routes, which helps inform decisions about appropriate protective measures for the animal care workers. Finally, this study illustrates the need for a prompt risk assessment of any newly-emerging pathogenic microorganism to help control disease transmission, prevent occupational exposures, and protect the public health.

6IB.9

Exposure of Cynomolgus Macaques To Small Particle Aerosols Containing H5N1 Avian Influenza Triggers Rapid, Lethal Acute Respiratory Distress Syndrome. DOUGLAS REED, Elizabeth Wonderlich, Katherine O' Malley, Jennifer Bowling, Amy Hartman, Jonathan Carney, Charles Scanga, Daniel Perez, Simon Barratt-Boyes, *University of Pittsburgh*

Avian influenza viruses including H5N1 and H7N9 can trigger severe, often fatal disease in humans. Severe viral pneumonia caused by H5N1 or H7N9 is thought to be a lower respiratory tract disease whereas seasonal influenza is a upper respiratory tract disease. Intratracheal and/or intranasal inoculation of virus only rarely results in severe, lethal disease in cynomolgus macaques. We developed a system for aerosol exposure of macaques to a highly pathogenic avian influenza virus, H5N1 (A/Vietnam/1203/2004). Macaques were exposed in a head-only chamber side a class III biological safety cabinet in the regional biocontainment laboratory at ABSL-3+. Aerosols were generated with an Aeroneb vibrating mesh nebulizer (Aerogen, Deerfield, IL) controlled by the AeroMP aerosol exposure system (Biaera Technologies, Hagerstown, MD). Aerosol sampling was accomplished using an all-glass impinger (Ace Glass, Vineland, NJ) and Aerodynamic Particle Sizer (TSi, Inc, Shoreview, MD). Initial studies prior to macaque exposures demonstrated that for virus aerosols the Aeroneb was consistently superior to the Collison 3-jet as measured by spray factor. Relative to fluorescein, there was little or no loss of influenza with the Aeroneb compared to a >90% loss of influenza with the Collison 3-jet nebulizer. Particle sizes generated by the Aeroneb were in the respirable range that would reach the deep lung. Within 18 hours of infection, macaques were febrile and there were significant changes in respiratory function which worsened on days 2 and 3. PET/CT imaging at 48 hours revealed a considerable inflammatory response in the lung. Mean time to death was 72 hours post-infection. Pathological and clinical findings all suggest the cause of death is acute respiratory distress syndrome (ARDS) which strongly represents what is seen in humans. Even at aerosol doses 10-fold lower than had previously been reported for other routes of inoculation, the disease was rapid and fatal in macaques. This new nonhuman primate model will be useful for developing and testing new vaccine or therapeutic approaches to treat severe human disease caused by avian influenza viruses.

6IM.1

Detection of Polyaromatic Hydrocarbons, as Well as Positive and Negative Inorganic Ions from the Same, Individual Particle. Johannes Passig, Julian Schade, Robert Irsig, Sven Ehlert, Martin Sklorz, RALF ZIMMERMANN, *Helmholtz Zentrum Munich and Rostock University*

Air pollution represents the largest environmental risk to health worldwide. Herein inhalation of polyaromatic hydrocarbons (PAHs) is an established cause of morbidity and mortality, but little is known about their detailed distribution in ambient particulate matter (PM). These details, e.g. the PAHs mixing state, are crucial for potential effects since PAHs may be equally distributed over a large particle ensemble or could be confined to a specific particle sub-type with high concentration producing strong local effects in the lung. Furthermore, PAHs are considered for taking an active role in secondary aerosol formation. As a consequence, novel aerosol characterization techniques that address PAHs on a single particle basis while providing information on their potential source are highly desired.

On-line techniques for individual particle profiling typically base on the Aerosol Time-of-Flight (ATOF) technique, which applies laser-desorption/ionization (LDI) of individual particles in the ion source of a bipolar mass spectrometer. Particle LDI is often limited to refractory inorganic compounds, while particle-bound molecules are typically fragmented. Approaches targeting on PAHs could not preserve the normal LDI-information on the inorganic bulk composition. Recently, we were able to complement the PAH information by positive inorganic ions from LDI using a complex laser ionization scheme. Here we present a route to obtain the full LDI information of both positive and negative inorganic ions in combination with PAHs. Thus, a conventional source apportionment that bases on ions of either charge can be combined with a fully-fledged PAH mass spectrum of individual particles.

Performance of a New VOCUS-PTRTOF for Detecting Volatile-, Semi-Volatile and Low-Volatile Organic Compounds.

PEKKA RANTALA, Matthieu Riva, Jordan Krechmer, Yanjun Zhang, Olga Garmash, Liine Heikkinen, Felipe Lopez-Hilfiker, Otso Peräkyla, Yonghong Wang, Mikael Ehn, *University of Helsinki*

Volatile organic compounds (VOCs) have a major impact on aerosol particle formation in the atmosphere. The development of new instruments – mainly mass spectrometers –, has brought new information to better understand the process chain from VOC emissions to oxidized compounds and condensation onto aerosol particles. However, to quantify each step of these chemical and physical processes, it is crucial to measure not only VOCs but also the wide variety of oxidation products from low to highly oxygenated molecules (HOMs).

Usually, the gas-phase measurements have been conducted using mass spectrometry with several different inlet designs to fill all the gaps between VOCs and HOMs. However, this is problematic in many ways. Calibrating all the instruments in a comprehensive way has remained especially challenging. In addition, operating several instruments is laborious, and availability of space and electricity can also be limited in remote locations. Therefore, instruments that can measure a wider range of compounds would be of great interest.

VOCUS PTR-TOF (proton transfer reaction time-of-flight mass spectrometer, TOFWERK AG/Aerodyne Research, Inc.) is a new instrument for detecting volatile organic compounds. The instrument is based on a new PTR-inlet design with sub-ppt detection limits. In December 2017, we organized a laboratory campaign, in which we explored the capability of the VOCUS to simultaneously measure α-pinene oxidation products generated from the ozonolysis of α-pinene under a wide variety of experimental conditions. Chemical characterization of gas-phase products was compared to several other types of chemical ionization mass spectrometers.

While data processing is still under way, first results indicate sensitive detection of the precursor and oxidized monomers (e.g. $C_{10}H_xO_{<8}$). For more oxidized products and/or dimers, the VOCUS either cannot measure these compounds or the instrument must be tuned more carefully to optimize its performance for these molecules.

Factors Affecting the Detection of Fine Particles by Secondary Nanoelectropray Ionization High Resolution Mass Spectrometry. Dandan Jin, Anthony S. Wexler, Jiafa Zeng, Man Nin Chan, Zhen Zhou, Yong Jie Li, XUE LI, *Jinan University*

Chemical characterization of aerosol particles at a molecular level is crucial to obtain a better understanding of their impacts on atmospheric chemistry, global climate and human health. Real-time mass spectrometry (MS) based methods have attracted attention due to their merits, which include high time resolution (seconds to minutes), minimization of artifacts resulted from condensation/evaporation during sample pretreatment and avoidance of time-consuming sample pretreatment. Recent studies have indicated that a soft ionization MS technique, secondary/extractive electrospray ionization MS (SESI/EESI-MS) is a promising alternative for the characterization of organic aerosol particles at the molecular level. However, ionization of particle-phase compounds in SESI is quite different from that in gas phase and the procedure is more complicated. Thus, investigations are needed into relevant SESI-MS operating parameters that improve sensitivity, selectivity and user-friendliness. In this study, a secondary nano-electrospray ionization (Sec-nanoESI) source was constructed and coupled with a high resolution quadrupole Orbitrap mass spectrometer (HRMS) for measurements of aerosol phase tartaric acid. Factors affecting the detection of TA particles using Sec-nanoESI-HRMS are systematically investigated and discussed. Temperature of the ion transport tubing (ITT) has the most pronounced impact on ion signal intensity, which may be ascribed to more efficient desolvation and ionization; normalized collision energy (NCE) applied in MS/MS measurement is also a parameter to be tuned to obtain the optimal fragment for quantitative analysis with higher specificity and sensitivity. By using the developed method, high sensitivity (a detection limit of 0.078 μg/m3) and a wide linear range (0–1.686 μg/m^3) of TA detection was achieved, providing a proof-of-concept demonstration for our Sec-nanoESI-HRMS in real-time measurements of atmospheric particulate organic matter.

6IM.4

Mechanistic Insights into the Ionization of Airborne Nanoparticles via Droplet Assisted Ionization (DAI). DEVAN E. KERECMAN, Michael J. Apsokardu, Murray Johnston, *University of Delaware*

Online methods for molecular analysis of secondary organic aerosol have the potential for fast time resolution measurements while consuming a minimal amount of sample. Understanding the ionization mechanisms behind these techniques allows for their optimization and successful application. Our group has developed an online technique, Droplet Assisted Ionization (DAI), where liquid droplets are sampled through a heated capillary into the mass spectrometer. The solvent medium assists formation of ions from analytes in the droplet, but the ionization mechanism and corresponding experimental conditions required for optimum detection are poorly understood. Current theories regarding the mechanism of DAI suggest an ionization process similar to electrospray ionization, but do not clearly explain how the initial charge is induced on the droplet. The work described here offers insight into the ion formation process by using two peptide-based aerosols, bradykinin and angiotensin II, as well as a polymer-based aerosol, poly(propylene)-glycol. The ion signal is found to increase linearly with aerosol mass concentration. There is no particle size dependence other than the fact that a large particle has more mass (and gives a correspondingly higher signal) than a small particle. A detectable signal is obtained for an aerosol mass flow into the inlet of about 80 pg/s. For the peptide aerosols, water is crucial for ionization. Drying an aqueous aerosol to remove water decreases the analyte signal intensity by 2-3 orders of magnitude. A similar reduction in signal intensity is observed when drying droplets composed of 50/50 water/acetonitrile solvent. Inlet temperature has a smaller but still important effect: signals are about an order of magnitude higher for inlet temperatures above 500 C than for lower temperatures. We find that additives, which increase the ion yield in a conventional inlet ionization experiment (e.g. 3-nitrobenzonitrile in Matrix Assisted Ionization, MAI), have little or no effect in DAI. This result suggests that such additives in a conventional experiment serve the purpose to create an aerosol, which is not needed in our work since aerosols are already being analyzed. The results of this study elucidate the conditions for efficient analysis of secondary organic aerosol by DAI.

6IM.5

Utilizing Bromide Chemical Ionization Technique in Detecting Oxidized Organic Compounds. Xucheng He, YEE JUN THAM, Siddharth Iyer, Mikko Sipilä, Matti Rissanen, *University of Helsinki*

Highly oxidized multifunctional (HOM) compounds have been found to play a crucial role in the atmospheric aerosol formation[1] and yet, direct measurement of many of these oxidized organics in the ambient air has remained challenging. Mass spectrometric methods using nitrate ionization[1], iodide ionization[2], and protonated water clusters[3] have been recently applied for direct detection of highly oxidized organic molecules in laboratory and field studies.

In this work, we explore the possibility of using a bromide chemical ionization technique to detect oxidized organic compounds. A Chemical Ionization Atmospheric Pressure interface Time-Of-Flight (CI-APi-ToF) was optimized to operate using bromide as the reagent ion. A series of test runs and calibrations for the instrument were conducted in our laboratory and scientific experiments were carried out in the CLOUD chamber in CERN. The results show that the bromide chemical ionization technique can detect a broad range of oxidation products; in form of $C_xH_yO_z^-$ and/or $(C_xH_yO_z)Br^-$ from oxidation of alpha-pinene (by O_3 and OH) under various temperature conditions. An interesting observation is that the hydrogen numbers in most of the deprotonated/dehydroxylated organic ions are odd, indicating that the bromide ionization process has stripped off one hydrogen atom (deprotonation) or potentially together with an oxygen atom (dehydroxylation) from the neutral molecules, which were not widely observed with the nitrate ionization method. The detected oxidized organic ions from bromide CIMS were compared with HOM species detected by a nitrate CIMS to examine if they present the same molecular structure or not under different experimental conditions (i.e. with or without NO_x). Another question that arose from our observations is whether the deprotonated/dehydroxylated ions and the organic-bromide cluster ions represent the same oxidation products, but are charged by a different mechanism (i.e., clustering vs charge transfer reaction), or are they compounds with same chemical formula but with a different chemical structure, i.e., are they isomeric products.

Overall, our study shows that the bromide ionization technique can detect a wider range of oxidized organic species, especially lower-oxidized species, compared to the nitrate CIMS. The comparison between the two ionization methods also helped shed light on the molecular structure of the detected oxidized organic species.

Chemical Composition of Atmospheric Ion Clusters Measured with the New ioniAPi-TOF. Markus Leiminger, Paul Mutschlechner, Daniel Gunsch, Arttu Ylisirniö, Stefan Feil, Alfons Jordan, Siegfried Schobesberger, Armin Hansel, GERHARD STEINER, *University of Innsbruck*

The Atmospheric-Pressure-interface developed by Tofwerk AG, Thun (Switzerland), for Time-of-Flight mass spectrometry (APi-TOF MS) is a technique especially suited to the detection of very low number concentrations of ions (a few hundred per cubic centimetre) in the atmosphere for subsequent identification of their chemical composition.

The Atmospheric-Pressure-interface of the new ioniAPi-TOF from Ionicon Analytik GmbH, consists of two hexapole ion guides, followed by an Einzel-lens system and an orthogonal acceleration time-of-flight mass analyser. The mass resolution m/Δm of the instrument is larger than 2000 (FWHM) with a total ion transmission of about 1%. The hexapoles used in this instrument allow for an almost constant ion transmission over a wider mass range than observed before. In the context of atmospheric ion clusters, this means that not only high-mass cluster ions, but also the composition of precursor compounds and gas-phase impurities can be measured simultaneously. Using hexapole ion guides in the ioniAPi-TOF results in rather low fragmentation of weakly bonded cluster ions. Increasing the DC voltage of the second hexapole allows the study of collision induced fragmentation of weakly bonded cluster ions.

We will present first results of the positive ion composition obtained under very well controlled conditions during the CLOUD 12 campaign in fall 2017 at CERN, studying the influence of galactic cosmic rays on new particle formation. In addition, we will show results from an inter-comparison with the Tofwerk AG quadrupole APi-TOF of the University of Eastern Finland and discuss differences in the lower mass range <100 Th and similarities in the operational performance of the instruments in the mass range > 100 Th.

Acknowledgements: We thank the CLOUD collaboration (www.cern.ch/cloud) for the opportunity to test the new prototype instrument and for their support. This work is funded by the Austrian Science Fund, FWF (project no. P27295-N20), the Tiroler Wissenschaftsfonds (nanoTOF-ICE) and the University of Innsbruck promotion grant for young researchers.

Aerosol Chemistry Investigations by CHARON-PTR-ToF-MS. MARKUS MUELLER, Joris Leglise, Tobias Otto, Todd Rogers, Armin Wisthaler, *IONICON Analytik GmbH., Innsbruck, Austria*

Scientific progress in organic aerosol chemistry is still hampered by the lack of analytical methods that comprehensively and quantitatively characterize the organic composition of particulate matter in the atmosphere. Recently, the "Chemical Analysis of Aerosol Online" (CHARON) particle inlet has been introduced, enabling proton-transfer-reaction time-of-flight mass spectrometry (PTR-ToF-MS) instruments to characterize particulate-bound organics down to pg m^{-3} levels. Herein, we will demonstrate the potential of the CHARON-PTR-ToF-MS for aerosol chemistry and physics studies. Based on results from experiments on 36 pure compounds we will show how qualitative (elemental composition) and quantitative analyses (mass concentrations) can be corrected for biases caused by analyte ion fragmentation in the PTR-ToF-MS analyzer. We will further show how bulk elemental ratios (O:C, H:C) of urban aerosol and monoterpene-derived SOA compare with parallel TOF-AMS measurements and reported literature values. We will also compare the volatility of monoterpene-derived SOA on a molecular level as directly measured in thermodenuder experiments and predicted from the 2D-volatility basis set using the CHARON-PTR-ToF-MS-derived chemical composition. The implications for the aerosol chemistry of monoterpene-derived SOA will be discussed.

The development of CHARON was funded through the PIMMS ITN, which was supported by the European Commission's 7th Framework Programme under grant agreement number 287382. J.L. and T.O. received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement number 690958 (MARSU).

An Overview on Evaluation of the New Capture Vaporizer for Aerosol Mass Spectrometers (AMS). WEIWEI HU, Pedro Campuzano-Jost, Douglas Day, Benjamin A. Nault, Taehyun Park, Taehyoung Lee, Aki Pajunoja, Annele Virtanen, Philip Croteau, Manjula Canagaratna, John Jayne, Douglas Worsnop, Jose-Luis Jimenez, *CIRES, University of Colorado, Boulder*

The Aerosol Mass Spectrometer (AMS) and Aerosol Chemical Speciation Monitor (ACSM) are widely used for quantifying submicron aerosol mass concentration and composition. Using the standard vaporizer (SV) installed in almost all currently-operating instruments, a collection efficiency (CE) correction, varying with aerosol phase and chemical composition, is needed to account for particle bounce losses, which dominate the uncertainty on quantification of concentrations. To address this limitation, a new capture vaporizer (CV) was recently built and tested in various laboratory and field measurements. Here, we present an overview of results on CV quantification and spectrum characterization for laboratory-generated compounds and ambient aerosols, with comparisons results from co-sampled SV-AMS and other independent measurement. We found CV-AMS has an improved CE for less volatile compounds (e.g., pure $(NH_4)_2SO_4$ in the lab) and achieves CE~1 for ambient aerosols. However, the CV chemical detection properties show some differences from the SV due to the increased residence time of particles and vaporized molecules inside the CV, and different vaporizer materials. The effects of oxidation and heating of aerosols on quantification using both vaporizers is also examined. Artifact CO^+ ions (and to a lesser extent, H_2O^+), when sampling long chain reduced OA (e.g. squalene) in the CV, are observed, probably caused by chemical reactions between sampled OA and molybdenum oxides on the vaporizer surfaces (with the carbon derived from the incident OA). No evidence for such CO^+ enhancement is observed for highly oxidized species and ambient OA. The elemental composition and source apportionment (PMF) with the CV can be accurately determined after proper calibration. The size distribution broadening is significant for monodisperse particles, but its impact is limited in field studies since ambient distributions are typically quite broad. Consistent size distributions of ambient aerosols were measured with the SV and CV after calibration. Finally, we summarize all the relevant pros and cons when using the CV versus SV.

6MS.1

Facile Synthesis of Magnetic Metal-Organic Framework Nanocomposites by Spray-Assisted Synthesis. MASARU KUBO, Manabu Shimada, *Hiroshima University*

Metal-organic frameworks (MOFs), which are the novel porous crystalline materials constructed by coordination bonds of metal ions and organic linkers, serve as promising materials for many applications such as adsorption and separation, catalysis, chemical sensing, and solar cell; owing to their excellent porous characteristics. Recently, integration of other functional materials into MOF structure is of keen interest to express synergistic effect. Especially, the incorporation of magnetic Fe_3O_4 nanoparticles into MOFs enables to deliver MOF materials by external magnetic field. The magnetic manipulation can be utilized for applications such as drug delivery, catalysis, adsorption and detection. The combination of MOFs and Fe_3O_4 nanoparticles have been realized by direct synthesis into MOF pore or heterogeneous growth of MOF onto the surface of Fe_3O_4 nanoparticles. However both techniques are inevitable to generate MOFs not incorporating Fe3O4 nanoparticles.

Recently we developed a new MOF synthesis method called a spray-assisted synthesis.[1] In this method, an MOF precursor solution is sprayed and subsequently dried to enhance a self-assembly of metal ions and organic linkers; which enables to form MOF nanoparticulate powder within 10 ms continuously. Generally, one-droplet-to-one-particles conversion is considered to be the typical particle formation in a spray based material processing. We considered that addition of Fe_3O_4 nanoparticles into an MOF precursor solution enables to disperse Fe_3O_4 nanoparticles in all sprayed droplet and in all MOF particles.

Hence , in this presentation, we demonstrate the synthesis of Fe_3O_4/MOF nanocomposite and their dye adsorption properties.

Dynamics of Carbon Nanotube Aerogel Formation. Christian Hoecker, Bhalerao Ajinkya, Nikolaos Kateris, Jean de La Verpilliere, Brian Graves, ADAM M BOIES, *University of Cambridge, University of Minnesota*

The underlying mechanisms behind the formation of gas-phase synthesized carbon nanotube (CNT) aerogels within a floating-catalyst chemical vapour deposition (FCCVD) reactor are still not well understood. The production of a macroscopic material from nano components, allows for the process to produce continuous CNT materials that are in great demand. The mass-produced self-assembled CNTs have superior thermal, electrical and mechanical properties making them valuable for many industrial applications.

While the material properties and applications of mass-produced CNT aerogels are well documented, the criteria required for gelation have not been discovered. Attempts have been made to describe CNT aerogel formation by relating the individual CNT growth to particle size distributions in the reactor. These, however, disregard fundamental features of 1-D material collisions, CNT restructuring and the dynamics within the FCCVD reactor.

In this presentation, we report on the dynamics of 1-D materials undergoing Brownian motion, collisions and re-orientation. By employing both molecular dynamic and Langevin dynamic modelling, we demonstrate that under typical conditions the time-scale for collision is much longer than the time-scale for re-orientation of the CNTs. Upon collision the CNTs re-orient to align with each other to form bundles (5-20 CNTs/bundle) due to Van der Waals forces. At a critical dimension, the CNT bundling ceases and long-range connections are maintained, thus allowing the formation of an aerogel.

Our work demonstrates the dynamics of both CNT collisions and bundling. Langevin dynamic results show that CNT collisions when accounting for both translation and rotation are similar to those found for non-dimensional aggregate collisions when only translation is accounted for. Molecular dynamics modelling demonstrates that re-orientation occurs at short timescales, but grows with CNT length and diameter. The methods for molecular dynamic modelling of re-orientation are discussed and approaches to extend the length of CNTs within a reasonable computational time are presented.

The resulting bundles and gelation theories are used to describe the aggregation in CNT aerosols which eventually leads to an aerogel formed of CNTs within synthesis reactors. These findings can then, for example, be related to the continuous gas phase process for the bulk production of CNTs, to identify the critical length and number concentration of CNTs required for gelation. Identifying the critical criteria for aerogelation of 1-D materials will potentially unlock the ability to produce novel self-assembled materials in high throughput reactors, unlocking the potential for industrial scale up.

6MS.3

Growth of Sub-5 nm Metal Nanoclusters in Polymer Melt Aerosol Droplets. Yong Yang, Pankaj Ghildiyal, MICHAEL ZACHARIAH, *University of Maryland, College Park*

Ultrasmall metal nanoparticles are inherently unstable because of their high specific surface area. This work investigates how growth and aggregation of these nanostructures can be circumvented by incorporating them into a polymer matrix in an on-the-fly growth process. We demonstrate the formation of sub- 5 nm particles of Ni, Co and Cu nanoparticles in polymer matrix using an aerosol single-drop reactor approach. The rapid thermal pulse given to the aerosol particles enables the formation of nuclei and growth, with subsequent rapid quenching to freeze in the structure. The role of temperature as well as precursor concentration of the resulting size and morphology are discussed. A characteristic time analysis and an analysis of the particle size distributions lead to the conclusion that growth is governed by nucleation and surface growth with little coagulation or Ostwald ripening. Finally, we note that this aerosol route is amenable to scale-up for large scale production of nanoclusters that can either be used as is within the polymer or released by solvent extraction, depending on application.

6MS.4

Single Step Synthesis of N/Ti3+ Co-Doped TiO2 Photocatalyst in a Flowing Microdroplet. LIANG-YI LIN, Shalinee Kavadiya, Yao Nie, Bedia Begum Karakocak, Pratim Biswas, *Washington University in St. Louis*

TiO2 has been widely investigated as a semiconductor photocatalyst in many areas like air/water purification, hydrogen energy, and conversion of carbon dioxide into fuels (e.g., CO and CH4). Nevertheless, the realization of TiO2 materials for practical uses has been impeded by its insufficient catalytic efficiency, which mainly originates from the fast recombination of photogenerated electron-hole pairs. Moreover, its wide band gap (~3.2 eV) makes it active only in the UV region, so it does not to utilize most of the solar spectrum. In this study, a visible-light-active nitrogen (N)/Ti3+ codoped TiO2 particle is developed for CO2 photoreduction. The N/Ti3+-TiO2 is directly synthesized in micrometer-sized droplets through a simple and continuous furnace aerosol process for the first time. Titanium nitrate and hydrazine monohydrate are used as precursors. The UV-Vis results revealed that the band gap of the aerosol-made N/Ti3+-TiO2 was drastically reduced to 1.53 eV, much lower than that of the pristine TiO2. And the photocatalytic activity tests showed that the N/Ti3+-TiO2 displayed an average CO production rate of 47.2 µmol g-1 h-1, which is about 8.9 times as high as that of commercial Degussa-P25 under UV-Vis-NIR light. The crystallinity, bandgap, and surface defect of the material were tailored by manipulating the furnace temperature and N2H4/Ti molar ratio, and detailed analyses on the physicochemical properties and the structure-photoactivity relationship of the obtained materials are systematically investigated. This study provides a new insight into the design of high-performance semiconductor materials for a wide range photocatalytic applications.

6MS.5

Aerosol-assisted Synthesis of a Stable Perovskite Absorber Layer for Application in Photovoltaics. SHALINEE KAVADIYA, Joseph Strzalka, Robin Wheelus, Pratim Biswas, *Washington University in St. Louis*

Recent advances have enabled aerosol generation techniques to synthesize and deposit materials for various applications. These techniques are simple, scalable, and operate at atmospheric pressure. Moreover, they can be operated continuously and allow precise control of material properties (size, morphology, crystal structure, composition), which are the challenges for some of the solution-based techniques. Perovskite ($CH_3NH_3PbI_3$) solar cells have received huge attention from the solar photovoltaic community in past few years because of their high efficiency and low-cost fabrication. However, their poor stability in ambient condition (mainly humidity) hinders their outdoor application. The presentation will discuss an aerosol-based technique, electrohydrodynamic atomization (i.e., electrospray), for fabrication of highly stable perovskite layer of perovskite solar cells under ambient humidity (30-50% relative humidity).

A two-step deposition method is used to form the perovskite layer, where PbI_2 is spin coated, and CH_3NH_3I (MAI) is electro-sprayed on the PbI_2 layer at room temperature. Both the precursors then react and form perovskite ($CH_3NH_3PbI_3$). The key feature of this methodology is lowering the reaction rate between the two precursors by gradually supplying MAI in solid nanoparticle phase onto the PbI_2 layer. The slow reaction leads to the formation of smooth and moisture-resistant perovskite film compared to the film fabricated by conventional solution-based techniques such as spin coating. The stability of the devices under the ambient condition is tested for 5.5 months. The cells fabricated using the electrospray retain 75% of the initial efficiency on average. The presentation will further discuss change in the structural properties of perovskite under heat treatment, and highly humid environment ($\geq$ 80% relative humidity) investigated using in situ Grazing Incidence Wide Angle X-ray Scattering (GIWAXS) at Synchrotron Facility, Advanced Photon Source at Argonne National Laboratory.

Exploring the Impacts of Drying Dynamics on Final Particle/Granule Morphology Using a New Droplet Chain Instrument. JIM WALKER, Rachael E.H. Miles, Jonathan P. Reid, *University of Bristol*

The evaporative drying of droplets dispersed in a gas phase to form solid granules is a key process in a wide range of industrial applications, from spray drying to produce functional nano- and micro-particles, the delivery of pharmaceuticals for inhalation, spray painting, and food processing. For example, liquid milk, which has a short shelf-life, relatively high mass and requires refrigeration, is often spray dried to a powder prior to storage or transportation.

The structure and density adopted by a granule as the solvent evaporates can vary significantly depending on the dynamics of the drying process. For example, by varying the Peclet number (Pe), a measure of the relationship between the evaporation rate and diffusion rate of colloidal particles within the droplet, structures as diverse as crystals, encapsulated solids, hollow spheres and buckled/deformed/folded shapes can be formed. The desired granular structure and density varies depending on the application and an unexpected change in structure, such as buckling, can have unfavourable consequences for the efficacy of the product. The drying conditions which control granule morphology are still poorly understood.

In this work we use a new falling droplet chain instrument to resolve the rapid drying dynamics of individual droplets containing particle dispersions over their full evaporative lifetimes and compare with the resulting granule morphologies. We examine the conditions, such as initial droplet size, drying rate and the composition and concentration of the colloidal dispersion, required to form granules of different morphologies with particular attention paid to the conditions which result in granule buckling.

The instrument creates a continuous train of droplets, dispensed using a droplet-on-demand generator, which appears as a static chain when stroboscopically illuminated at the dispensing frequency [1]. The uniformity of the dispensed droplets and the reproducibility of the drying events means each droplet in the chain represents a subsequent snapshot in the lifetime of an individual droplet. The exceptional temporal resolution at which measurements can be made (10 ms) is calculated from the reciprocal of the dispensing frequency. High resolution imaging allow the drying dynamics to be resolved by measuring properties including the volume equivalent diameter (density independent), the aerodynamic diameter (density dependent) and optical diameter with < 1 um accuracies. The initial droplet diameter, typically 30 – 80 µm, can be controlled by the dispenser and the evaporation rate controlled with a temperature controlled gas flow. The final granule morphologies are examined using offline analysis tools such as scanning electron microscopy (SEM).

Synthesis of Nanoscale Composite of Inorganic Elements And Aerosol Based Delivery for Improving Plant Nutrition.

RAMESH RALIYA, Pratim Biswas, *Washington University in St. Louis*

Nanomaterials are being investigated for addressing food – energy and water nexus. However, the majority of such published literature used either single or two type of nanoscale materials mixture. Naturally, plants uptake multiple elements altogether from soil – nutrient mixture, therefore, we designed our experiments to mimic nutrient mixture of highly required nutrients sources. In the present investigation, we synthesized using an aerosol process a nanoscale composite of five active nanoscale materials of nitrogen, phosphorous, potassium, zinc, iron which were loaded in the nano-porous silica particles. The mean geometric size of the nutrient loaded particles were in a range between 150 and 200 nm. The synthesized particles were characterized for the physicochemical properties and long term-stability using electron microscopy, X-Ray diffraction, dynamic light scattering and photo-correlation spectroscopy. The synthesized particles were applied on jalapeno pepper plants using an advanced aerosol delivery approach and studied through the life cycle. We observed significant improvement in plant growth, development, flowering, number of fruits and their nutritional contents. In summary, the carefully synthesized composite of active nanomaterial, aerosol-based foliar delivery to plant leaves and their systematic release may have potential not only to improve crop production but overall to address food-energy-water-environment nexus.

6MS.8

Polymer Coating of Inorganic Semiconductor Nanoparticles by Aerosol Approach. Masoom Shaban, Jalal Poostforooshan, ALFRED P. WEBER, *TU Clausthal*

Polymer coated inorganic semiconductor nanoparticles (ISNs) have attracted great attention due to enormous applications such as biomedical, catalysis, electronics, etc. Generally, the ISNs−polymer nanohybrids have been synthesized in the liquid phase methods which an appropriate solvent and surfactants are always required and they include several time-consuming steps. Moreover, in order to improve the compatibility between ISNs and monomers, suitable surface modification of inorganic nanoparticles is usually necessary.

To overcome the drawbacks of conventional wet methods, the work presented here describes a novel and facile approach to produce various ISNs−polymer core-shell including ZnO, TiO_2, and Fe_3O_4 nanoparticles by a surfactant-free aerosol-based synthesis *[1]*. In this regard, fresh spherical ZnO nanoparticles were initially generated by spark discharge followed by the sintering furnace in the gas phase. The size distributions of the spark generated ZnO nanoparticles sintered at different temperatures were measured using a scanning mobility particle sizer (SMPS).

The resulting ZnO nanoparticles exhibit excellent performance in the photocatalytic surface-initiated polymerization of butyl acrylate monomer in the continuous aerosol–photopolymerization, within the average aerosol residence time of 35 s in the photoreactor. This method is based on heterogeneous condensation of monomer vapor around the surface of gas-born ISNs, which is then polymerized ‘‘in flight’’ under UV light irradiation. In this one-pot synthesis, ISNs act not only as inorganic cores, but also at the same time are able to release charge carriers (electron-hole pairs) upon photoexcitation which drive the free radical polymerization near their surface. Therefore, no added initiator is required. To further investigate the basis and the mechanism of our experimental results, the optical properties of ZnO nanoparticles during the UV irradiation in the gas phase process was simulated by a three-dimensional finite difference time-domain (FDTD) method. Moreover, the coating efficiency was evaluated by aerosol photoemission and the results demonstrate that monomer and polymer coating efficiency are 99% and 80%, respectively.

Then, to verify the generality of this method toward coating different kinds of ISNs, rod-like ZnO, TiO_2 P25, and magnetic Fe_3O_4 nanoparticles were used as inorganic cores and photoinitiators. Interestingly, the thickness of polymer shell can be easily adjusted at the desired nanoscale by tuning the monomer vapor pressure. The molecular structure of the core-shell nanoparticles was characterized using ^1H NMR, FTIR, XRD and UV−vis spectroscopy. The polymer shell was also confirmed by TEM and XPS methods.

Finally, to investigate the potential applications of the nanohybrids in the fabrication of novel composites, the successful change in the surface hydrophobicity of ISNs after the encapsulation with the polymer shell was confirmed by their preference for an organic solvent.

High Throughput Synthesis of Aerosolized Poly(3,4-ethylenedioxythiophene) (PEDOT) Nanoparticles for Water Dispersible Colloids. Lu Yang, Clayton Kacica, Shinjita Acharya, Yifan Diao, Luciano Santino, Hongmin Wang, Pratim Biswas, JULIO D'ARCY, *Washington University in St. Louis*

The conducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) is an organic electronic that serves as the active species in a plethora of applications for storing and harvesting energy as well as for sensing biological reactions. Moreover, this flexible soft material is characterized by high physical and chemical stability and a controllable and reversible doping mechanism that results in robust device performance. Current synthetic strategies for producing PEDOT employ a radical oxidative polymerization that is commonly carried out via solution oxidation synthesis, electrochemistry, or vapor phase deposition. Here we demonstrate a cutting edge route for making PEDOT using aerosolized aqueous droplets of the oxidant FeCl3 that react with vapors of the monomer 3,4-ethylenedioxythiophene inside a tube reactor. Our scalable and continuous high throughput approach results in spherical nanoparticles of PEDOT that are electrically conducting with a 300 ohm surface resistance; PEDOT nanoparticles are dispersible in water without the need of additives or surfactants. Colloids produced are stabilized by the polymer surface charge and solution processed to fabricate electrochemically active electrodes that store energy. Here we correlate polymerization kinetics and residence time to a polymer's crystal structure and its electrochemical activity in pseudocapacitors. Our work demonstrates high throughput processing of 500 nm diameter particles in gram quantities for delivering both high energy and power densities. We believe that this aerosol synthesis paves the way for a new route to producing this commercially important soft material and highlights the versatility of aerosol synthesis for producing the next generation of conducting polymer nanostructures.

6TT.1

Machine Learning to Predict the Global Distribution of Aerosol Mixing State Metrics. Michael Hughes, Jack Kodros, Jeffrey R. Pierce, Matthew West, NICOLE RIEMER, *University of Illinois at Urbana-Champaign*

Atmospheric aerosols are evolving mixtures of chemical species, and the term "mixing state" is often used to characterize this mixture. A population in which each particle is composed of one chemical species is called externally mixed, one where all particles are the same mixture of species is internally mixed, and real populations lie in between. In global climate models (GCMs) the aerosol mixing state is represented in a highly simplified manner. For example, modal models represent all aerosols within a given mode as internally mixed, while different modes are considered externally mixed. Failing to capture the true aerosol mixing state of ambient aerosols can introduce errors in the estimates of climate-relevant aerosol properties, such as the concentration of cloud condensation nuclei.

The goal for this study is to determine a global spatial distribution of aerosol mixing state with respect to hygroscopicity, as quantified by the mixing state metric χ. In this way, areas can be identified where the external or internal mixture assumption is more appropriate. Calculating χ requires detailed per-particle composition information, which is not possible to directly predict in GCMs. We therefore used the output of a large ensemble of particle-resolved box model simulations in conjunction with machine learning techniques to train a model of the mixing state metric χ. This lower-order model for χ uses as inputs only variables known to GCMs, enabling us to create a global map of χ based on GCM data. We found that χ varied between 20% and nearly 100%, and we quantified how this depended on particle size, location, and time of the year. This framework demonstrates how machine learning can be applied to bridge the gap between detailed process modeling and a large-scale climate model.

6TT.2

Simulation of Heterogeneous Oxidation of SO2 and NOx in the Presence of Gobi Desert Dust Particles under Urban Environments.

ZECHEN YU, Myoseon Jang, *University of Florida*

Large quantities of mineral dust particles are frequently ejected into the atmosphere through wind action. The surface of mineral dust particles can act as an import sink for atmospheric tracers (i.e., O_3, SO_2, NO_x and hydrocarbons) and photochemically enhance the production of oxygenated compounds. The photochemically oxidized hydrocarbons in the gas phase partition onto dust particles and involve in dust-phase heterogeneous reactions. These products modulate the characteristics of dust surfaces. In this study, we simulate the oxidation of SO_2 and NO_x in the presence of mineral dust under the ambient conditions using the Atmospheric Mineral Aerosol Reaction (AMAR) model. The model consists of explicit reaction mechanisms in three phases: gas phase, inorganic salted aqueous phase, and dust phase. Dust heterogeneous chemistry begins with a gas-particle partitioning process and is further processed *via* both autoxidation and photocatalytic oxidation by the dust phase semi-conducting matters. The simulation using the model is compared with UF-APHOR chamber data for the formation of nitrate and sulfate in the presence of Gobi Desert Dust particles and different hydrocarbons (i.e., 2-Methyl-2-butene, alpha-pinene, toluene, isoprene, gasoline and urbane mix hydrocarbons). In the exploratory experiment, the organic compounds formed from the photooxidation of 2-Methyl-2-butene in the presence of NO_x showed a negligible effect on dust-phase nitrate formation. However, oxidized compounds formed from the photooxidation of secondary organic aerosol precursor hydrocarbons (i.e., alpha-pinene) depleted dust phase nitrate that formed *via* the reaction of alkaline carbonates with nitric acid. The adsorbed ozone on dust surfaces can positively modulate the formation of sulfate and nitrate. Using the AMAR model that is integrated with the Carbon Bond mechanism (CB6), the influence of ozone on sulfate and nitrate formation in dust particles will also be simulated under the urban environments that contain various hydrocarbons and NO_x.

6TT.3

Photochemical Model Estimated Fire Impacts on Aerosol Evaluated with Field Studies and Routine Data Sources. KIRK BAKER, *United States Environmental Protection Agency*

Highly instrumented field studies provide a unique opportunity to evaluate multiple aspects of photochemical grid model representation of fire emissions, dispersion, and chemical evolution. Fuel information and burn area for a specific fire coupled with near-fire and downwind chemical measurements provides information needed to constrain model predicted fire plume transport and chemical evolution of important pollutants such as particulate matter (PM2.5) that have deleterious health effects. Most local to regional scale field campaigns to date have made relatively few transects through plumes from fires with well characterized fuel type and consumption. While more comprehensive field studies are being planned for 2018 and beyond (WE-CAN and FIREX), existing measurement data from multiple field campaigns including 2013 SEAC4RS, satellite data, and routine surface networks are used to assess how a regulatory modeling system captures fire impacts on local to regional scale PM2.5. A comparison of Community Multiscale Air Quality (CMAQ) model estimated speciated PM2.5 from specific fires with routine surface measurements at rural locations in proximity to the 2013 Rim fire, 2011 Wallow fire, and 2011 Flint Hills fires indicate PM2.5 organic carbon tends to be overpredicted at rural surface sites downwind from the 2011 Flint Hills prescribed fires while results were mixed at rural sites downwind of the 2013 Rim fire and 2011 Wallow fire. These results suggest differences in fuel characterization (e.g., emission factors, emissions speciation, burn period, etc.) between these areas may contribute to differences in model prediction. Remotely sensed AOD and aircraft transects made downwind of the 2013 Rim fire suggest the model does well at predicting local to regional scale transport and also the vertical extent of the plume. However, the model tends to underestimate regional downwind AOD compared with satellites and ground-based estimates during the Rim fire period.

6TT.4

Effects of Near-Source Coagulation of Biomass Burning Aerosols on Global Predictions of Aerosol Size Distributions and Implications for Aerosol Radiative Effects.

EMILY RAMNARINE, Jack Kodros, Jeffrey R. Pierce, *Colorado State University*

Motivation: Biomass burning is a significant global source of aerosol number and mass. Aerosols scatter and absorb solar radiation along with potentially acting as cloud condensation nuclei, affecting cloud albedo and lifetime. These climatic effects are known as the direct radiative effect (DRE) and the cloud-albedo aerosol indirect effect (AIE), respectively. These effects are influenced by the size distribution of the aerosol. Coagulation of particles is an important process in determining this size distribution. As coagulation occurs, the number of particles is diminished and the distribution is shifted to a larger mean diameter.

Sakamoto et al. (2016) found that the rate of growth by coagulation of a single fire plume can be approximated using the emissions rate of biomass burning aerosol mass, initial size distribution median diameter and modal width, plume mixing depth, and wind speed. This parameterization is physically intuitive as more concentrated emissions or emissions that are harder to dilute (due to larger emissions fluxes, larger fires, smaller wind speed, or smaller mixing depth) lead to the signatures of faster coagulation.

Methods: To explore the effects that coagulation has on global aerosol size distributions, we incorporated this parameterization into GEOS-Chem, a global model, with TwO Moment Aerosol Sectional (TOMAS) microphysics and fire emissions from the Fire INventory from NCAR (FINN). In the default configuration of GEOS-Chem-TOMAS, the fire emissions are given a fixed size distribution regardless of fire characteristics and meteorology. We adjust this emitted size distribution by aging it for one day using the above parameterization while keeping the mass of emissions constant. We use the rapid radiative transfer model for global climate models (RRTMG) on our GEOS-Chem-TOMAS aerosol output to study the effect that coagulation has on the DRE and AIE.

Sensitivities simulations: We test the sensitivity to two major uncertainties in our simulations. First, the initial size distribution of biomass burning emissions is important to the coagulation parameterization, but is not well known. To address this uncertainty, we have tested a range of initial median diameters and lognormal modal widths. Another uncertainty regarding the subgrid smoke coagulation parameterization is how much the smoke plumes overlap while coagulation is occurring. Plumes that do not overlap dilute more quickly than those that overlap and hence have less coagulation. We look at the two extreme cases: all plumes in each gridcell overlap instantly, creating one large plume, or they do not overlap at all.

Results: Our main results are as follows. (1) When there is more coagulation there is generally a smaller number of particles overall, but in some locations there is a high number of particles at small diameters due to a microphysical feedback creating more nucleation. (2) In regions/cases with more subgrid coagulation, there is lower sensitivity to uncertainty in the initial size distribution. (3) Regions and cases with more coagulation have fewer CCN-sized particles, which leads to a decrease in the magnitude of the AIE of biomass burning particles, though the effect remains negative in all cases. (4) DRE due to biomass burning is negative but is not found to be sensitive to our assumed coagulation scheme or initial size distribution because the size distribution changes do not greatly impact the mass extinction efficiencies in our cases.

Recommendation: In order to improve our estimates of biomass burning size distributions and radiative effects, we need (1) estimates of how plumes merge and overlap in different regions and (2) improved estimates of emitted size distributions in different regions in our simulations.

Air Quality Impact of Distributed Combined Heat and Power Facilities. BO YANG, K. Max Zhang, *Cornell University*

Distributed generation (DG) has been more generally used to supply energy to the end users. Compared with centralized generation, DG has many advantages. Generating power on-site eliminates the cost, complexity and inefficiencies associated with transmission and distribution. However, since on-site DG facilities are close to the end users, the hydrocarbon fuelled DG emissions could be an important health issue.

The on-site air quality impacts of two different DG facilities on university campuses were investigated. One is a biomass fuelled combined heat and power (CHP) system equipped with an electrostatic precipitator (ESP). The other is a natural gas turbine CHP system with duct burners and a heat recovery steam generator (HRSG). For the biomass system, two rooftop sampling stations with $PM_{2.5}$ and CO_2 analyzers were established in such that one could capture the plume while the other one served as the background for comparison depending on the wind direction. Four sonic anemometers were deployed around the stack to quantify spatially and temporally resolved local wind patterns. For the natural gas turbine system, the in-stack emission tests were conducted in 2010 and 2015. $PM_{2.5}$, NO_x and other gas emissions were recorded. The emission data over time were analyzed by comparing these two sets of measurements.

A CFD-based model, Comprehensive Turbulent Aerosol Dynamics and Gas Chemistry (CTAG), was employed to analyze the measurement data and estimate the spatial variations of near-source pollutants. The primary $PM_{2.5}$ dispersion and chemical transformation of gaseous pollutants were simulate using the real terrain, local buildings, and meteorological data.

The simulation results demonstrated the near-ground “hotspots” would pose potential health risks to building occupants since ultrafine particles could penetrate indoors via infiltration, natural ventilation, and fresh air intakes on the rooftop of multiple buildings. Furthermore, spatial distributions of high ground level concentrations obtained by using CTAG were different from those by using a Gaussian-based parameterized model, AERMOD, largely due to that the CFD-based CTAG model can capture the building downwash effect much better than Gaussian-based models. Building downwash causes emissions entrainment inside wake zones next to buildings and lead to elevated local air quality impact, especially when the DG facilities have comparatively shorter stacks in an urban area. The implications on mitigating on-site air pollution and the suggestions on permitting DG facilities were discussed.

6TT.6

The Mixing State of Aerosol Particles in Asian Outflow Observed in the Spring of 2017. CUIZHI SUN, Kouji Adachi, Kentaro Misawa, Joe Hing Cho Cheung, Charles C.K. Chou, Nobuyuki Takegawa, *Tokyo Metropolitan University*

Anthropogenic emissions of aerosols and trace gases from East Asia have large influences on air quality and climate both on regional and global scales. The mixing state of black carbon (BC) aerosols, which is a key parameter for investigating the radiative impact of aerosols, has not been well understood because analytical methods for quantifying the mixing state of BC is limited. We have conducted an intensive measurement campaign in Taiwan in the spring of 2017, with the main focus being on the chemical composition and mixing state of aerosols in Asian outflow. The measurement was made at the Cape Fuguei (CAFE) station (25°N, 121°E) located on the northern tip of Taiwan from February 21 to March 14 in 2017. The laser induced incandescence-mass spectrometric analyzer (LII-MS) was used to measure the chemical composition of aerosol particles classified by the mixing state of BC. The combination of online LII-MS measurements and offline transmission electron microscope (TEM) analysis can provide useful insights into the variability in the mixing state of aerosols in Asian outflow. The other instruments include an Aerodyne mini aerosol mass spectrometer (mini-AMS), a particle-into-liquid sampler coupled with ion chromatography (PILS-IC), and filter sampling. A comparison of the LII-MS, mini-AMS, PILS-IC, and filter data demonstrates that sulfate, nitrate, and BC were quantified with reasonable accuracy.

Large enhancements in the mass concentration of PM2.5 aerosols were found during the measurement period. Backward trajectory analysis suggests that the enhancements were not due to local sources but to regional transport of air masses from the Asian continent. Sulfate was found to be the dominant chemical composition of fine mode aerosol particles. Nitrate was relatively minor in fine mode and abundant in coarse mode aerosols. The LII-MS data shows that the mass fraction of sulfate internally-mixed with BC was as high as 15% in highly polluted air masses. The variability in the mixing state of BC observed by the LII-MS was qualitatively consistent with that obtained from the TEM analysis. Factors affecting the variability and possible dependence of the LII-MS sensitivity to various types of mixing state (e.g., shell-core, attached) are discussed in detail.

Between Two Oceans: Auckland's Urban Aerosol. GUY COULSON, Gustavo Olivares, Sally Gray, Oliver Wilson, *National Inst of Water & Atmospheric Research, New Zealand*

Auckland, the largest city in New Zealand, is unique in being the largest city in the World to be almost completely surrounded by ocean and hence have no up or downwind sources of pollution. The city lies on a narrow isthmus between the Pacific Ocean and the Tasman Sea. Because of the lack of outside sources, average urban background concentrations of between 1000 and 4000 particles/cm3 are common away from major sources with very steep concentration gradients approaching sources such as roads (Pattinson et al., 2014). Consequently, Auckland's typical urban aerosol tends to be similar to other cities in character but with lower concentrations (Coulson et al 2015).

The Aerosol Tropospheric Chemistry in Urban Auckland (ATChU) experiment aimed to track the changes in aerosols and aerosol precursors as they move from open-ocean (clean background) across the city (polluted) and out into ocean again. Auckland has two prevailing wind directions WSW from the Tasman and ENE from the Pacific, so a transect along this line will almost always be in the prevailing wind direction. The experiment measured various aerosol parameters including composition, Black Carbon, particle number and size distributions along with gaseous pollutants simultaneously at three points across Urban Auckland, one on the upwind coastal urban edge, one in central Auckland and one on the downwind coastal urban edge for a period of approximately one month during March and April 2015.

Results from the west coast site have a similar character to the central Auckland site but with lower concentrations and a noticeable marine influence, whilst the east coast site has a more marine character with some urban influence. This presentation will examine results from the ATChU campaign with an emphasis on looking for the urban influence in a marine setting.

The Effect of Vegetation on the Deposition and Dispersion of Ultrafine Particles Carrying Different Charges. MING-YENG LIN, Gabriel Katul, Andrey Khlystov, Chia-Ren Chu, *National Cheng Kung University*

Ultrafine particles (UFP) continue to receive increased attention due to their dual role in cloud microphysics and human health. Charged UFP can contribute a significant fraction of total UFP concentration, yet their deposition onto vegetation remains a subject of inquiry. Given the areal coverage of vegetation over land, vegetation is commonly assumed to be a large sink for UFP. Despite its broad significance, previous laboratory studies mainly focused on neutral UFP deposition onto canopies. Here, wind tunnel experiments are used to investigate the effect of vegetation on the deposition and dispersion of UFP carrying different charges.

To characterize the effect of vegetation on the deposition of UFP (size range 12.6 – 102 nm) carrying different charge, a small wind tunnel was first used. Juniper branches (*Juniperus chinesis*) covered the entire working section of this wind tunnel (i.e., the air flow is only through vegetation) and particle collection was determined from concentration differences across the vegetation section. Three different wind speeds were used (0.3, 0.6, and 0.9 m/s) in the experiments and their results were interpreted using single fiber theory. Results indicate that single fiber theory can be used to represent deposition of singly-charged UFP onto vegetation if both the image force and Brownian diffusion are simultaneously considered.

To investigate the effect of roadway vegetation on the dispersion of UFP carrying different charge, a boundary layer wind tunnel was used in this experiment. A line source simulating traffic emission was constructed and different row of trees (zero, one, and two rows) were used to explore the effect 'vegetation barriers' on UFP dispersion. A Tandem Differential Mobility Analyzer (TDMA) system was employed to examine the dispersion of UFP carrying different charges downwind of the roadway vegetation. Three different wind speeds (1, 2, and 3 m/s) were also tested. Preliminary results indicate that charged UFP number concentration decreases downwind of the vegetation as expected, the decay rate of charged UFP is faster than neutral UFP. The study results provide guidance for future climate and air quality models incorporating UFP.

6TT.9

Improved Estimation of Organic Aerosol Volatility Distributions by Combining Thermodenuder and Isothermal Dilution Measurements. KERRIGAN CAIN, Eleni Karnezi, Spyros Pandis, *Carnegie Mellon University*

Volatility is one of the most important physical properties of organic aerosol (OA), as it determines the partitioning of its components between the gas and particulate phases and eventually, their atmospheric fate. Most studies have estimated the OA volatility distribution using a thermodenuder (TD); however, the resulting distributions were quite uncertain. In this work, we test the hypothesis that the combination of TD and dilution measurements can better constrain OA volatility distributions over a wide range.

In this study, the method of Louvaris et al. (2017) combining TD and isothermal dilution measurements was refined using secondary organic aerosol (SOA) generated from the ozonolysis and reaction with OH radicals of several different precursors. SOA was produced in a smog chamber and sampled with a TD followed by a high-resolution time-of-flight aerosol mass spectrometer (AMS) and a scanning mobility particle sizer (SMPS). Parallel to the TD, a dilution chamber partially filled with clean air was used to isothermally dilute the SOA. The mass fraction remaining as a function of TD temperature and time in the dilution chamber was monitored by the AMS and SMPS. Improved wall loss corrections were used in order to better account for evaporation in the dilution chamber. The thermograms were then used with the algorithm of Karnezi et al. (2014) to estimate the volatility distributions, effective enthalpies of vaporization, and accommodation coefficients of the SOA tested. The results indicated that TD measurements alone overestimate the amount of semi-volatile SOA components. Furthermore, when the dilution measurements were added, the uncertainties of the semi-volatile components and enthalpy of vaporization were reduced.

The combination of TD and dilution measurements shows improvement over current techniques to estimate OA volatility distributions and can be implemented easily into volatility studies already using a TD. The application of this technique to ambient aerosol can provide insight into OA volatility and the results can be used to update chemical transport models accordingly.

7AC.1

Hygroscopicity Dependent Upon Reaction Between Components in Internally Mixed Sodium Pyruvate and Ammonium Sulfate Aerosols. Hui Yang, PANG SHUFENG, Yunhong Zhang, *Beijing Institute of Technology*

In atmosphere, some compounds are mixed in a particle. The chemical reaction between components can lead to gas-particle repartition of volatile species, which has the important effect on SOA formation and climate. Herein, the reaction between sodium pyruvate and ammonium sulfate was monitored by using the attenuated total reflectance Fourier transform infrared (ATR-FTIR).

With decreasing RH, the feature bands of sodium pyruvate and ammonium sulfate decreased gradually, indicating a depletion of sodium pyruvate and ammonium sulfate. At 65.5 % RH, a sharp and narrow peak at 1132 cm−1 appeared, which is accompanied by the degration of the band at 1095 cm-1 into a weak shoulder, suggesting the formation of crystalline sodium sulfate. As the continuous decrease in RH, the 1132 cm-1 peak became stronger, indicating more crystal sodium sulfate. So it can be concluded that the reaction between sodium pyruvate and ammonium sulfate reduced to sodium sulfate and release of ammonia and pyruvic acid release.

When the RH take a cyclic change, water content decreased to ~50% or original droplets. In the second RH cycle, water content can restore. So the water content decrease should rise from the particulate reaction which ended after a RH cycle. Because of changeable compositions, the efflorescence RH on second dehumidifying was 67.1%, slightly higher than that of 64.2% on first dehydration.

7AC.2

Resolving the Factors Governing Particle Phase Photochemistry. BRYAN R. BZDEK, Lara Lalemi, *University of Bristol*

Whereas gas phase photochemistry and its role in producing new particles and determining gas phase composition are relatively well understood, aerosol phase photochemistry is understudied in part because of the complexity of the system. For example, nanofocussing of light into aerosol particles results in nonhomogeneous light distributions that are highly size dependent. Moreover, photochemistry at the solution-air (or particle-air) interface has been implicated in production of atmospherically significant volatile organic compounds that may even produce new atmospheric particles. Finally, aerosol particles can access supersaturated and highly viscous solute states, potentially changing the rates of photochemical reactions as well as the ability for the products to diffuse throughout the particle. The goal of this work is to resolve the factors that govern aerosol photochemistry (i.e. particle size, surface composition, and bulk properties) and compare them to bulk systems. These experiments will utilise holographic optical tweezers, where a laser beam is focussed through a microscope objective to produce one or several optical traps that will capture airborne picolitre volume droplets. Droplet size and refractive index can be precisely retrieved through collection of a Raman spectrum. Droplet surface and bulk properties are quantified through precise measurement of the coalescence dynamics of two optically trapped droplets.

The photolysis of nitrate will be used as a model system to probe photochemistry in aerosol particles. In a first set of experiments, the loss of the nitrate signal in the droplet Raman spectrum will be monitored as a function of exposure to UV light and particle size. A second set of experiments will examine how photolysis rates change as the droplet viscosity is increased by adding a known amount of sucrose to the droplet. A third set of experiments will resolve the significance of the aerosol-air interface to photochemistry. These experiments will involve incorporating a photoactive surfactant (e.g. nonanoic acid) into the droplet and monitoring changes to droplet properties as the surface coverage is changed. Together, these experiments will identify and quantify which factors are most significant to determining photochemical rates in aerosol droplets.

7AC.4

The Role of Solvent Environment on the Production of Imidazoles in Secondary Organic Aerosol Mimicking Solutions Containing Glyoxal and Ammonium Sulfate. ANDREW BERKE, Tara Bhat, Emma Gubbins, Hunter Myers, Amanda Nwankwo, *Smith College*

The reaction between glyoxal and ammonium sulfate represents an important model system with which to study the non-oxidative production of light absorbing compounds in secondary organic aerosols (SOAs). SOA particles have access to hundreds or thousands of airborne chemicals as they age, and each of these chemicals have the potential to affect particle growth, physical properties, and the production of light-absorbing compounds, such as imidazoles. These compounds can subsequently influence a particle's climatic and human health effects.

Our research seeks to understand the role the solvent environment, due to the addition of non-reactive chemicals, plays in SOA-forming bulk-phase reactions between glyoxal and ammonium sulfate. We use small, atmospherically relevant chemicals to perturb the solvent matrix and then measure the formation kinetics of light-absorbing compounds and solution viscosity of the resultant mixture. Results will be presented for a series of short-chain alcohols and other relevant organic molecules with different functional group moieties (including diols, ketones, esters, and nitriles) that show a relationship between solution viscosity and the production of imidazoles. Reasons for the observed behavior are also explored.

7AC.5

Investigating the Link between Molecular Mass, Volatility, and Optical Properties of Light-absorbing Organic Aerosols.

KHAIRALLAH ATWI, Zezhen Cheng, Rawad Saleh, *University of Georgia*

Organics produced from incomplete combustion span a wide range of light-absorption properties. We have directly investigated the relation between the light-absorption properties and molecular weight and volatility by conducting controlled combustion experiments using benzene as a model fuel. Combustion conditions were controlled by varying the flow rates of air and benzene and by controlling the temperature at which the combustion took place. At each combustion condition, the absorption coefficients (measured online using a photoacoustic spectrometer at 780, 532, and 420 nm) and the size distribution (measured using a scanning mobility particle sizer) were used to calculate the mass absorption cross section (MAC) and the absorption Ångström exponent (AAE). The particles were also collected on Quartz filters for offline analysis using laser desorption ionization time-of-flight mass-spectrometry (LDI-TOF-MS). The advantage of using LDI is that it can detect large molecules intact, allowing us to follow the formation of large organics from a several hundred to thousands of AMUs. Those measurements were also performed after heating the emissions in a thermodenuder operated at different temperatures to investigate the contribution of organics of different volatility to the total absorption cross section of the particles.

The light-absorption properties of the organic combustion particles generated spanned a wide spectrum, with MAC at 532 nm ranging from 0.4 to 2.4 m^2g^{-1} and AAE ranging from 9 to 3. The mass spectra produced using LDI-TOF-MS showed 24 AMU-spaced, regularly repeating peaks previously observed in the soot formation literature, with masses ranging between 200 and 2000 AMU. More importantly, there was a clear correlation of the molecular weight distribution of the organics with their light-absorption properties: the darker the samples (larger MAC and lower AAE), the more shifted were their mass spectra towards larger molecular sizes. Our experiments also show that as the particles were stripped of their more volatile components in the thermodenuder, their MAC increased and AAE decreased, indicating that the less volatile components are more absorptive. At a thermodenuder temperature of 400 C, the residual organics were extremely highly absorptive, with MAC and AAE of 3 m^2g^{-1} and 1.5, respectively. Furthermore, the mass spectra of the thermodenuded samples had a largely diminished signal in the low molecular weight region, indicating that they consist of larger compounds. These findings provide physical evidence of the relation between the molecular weight of the compounds and their volatility and optical properties, with volatility decreasing and light-absorption across all wavelengths increasing with increasing molecular weight.

7AC.6

Observations of Sulfate Aerosol Condensation in Flue Plumes from Coal-Fired Power Plants Equipped with WFGD.

JIANMIN CHEN, Xiang Ding, Di Wu, Xianmang Xu, Qing Li, *Fudan University*

More than half of the annual worldwide coal consumption is consumed in China, where about a half is used for electricity generation. Coal combustion is acknowledged to be one of the largest contributor to China’s haze pollution. Therefore, a new regulation for controlling air pollutant emissions from coal-fired power plants (CFPPs) has been executed in 2014. This policy has been called the standard of “Ultra Low Emission”. To meet the standard, all CFPPs are required to install flue gas desulphurization (FGD) and denitration systems. More than 90% of FGDs use the wet process of limestone-gypsum FGD technology, which is also the world’s most widely used FGD technology to remove SO2 and particulate matters (PMs). However, there is always a long “White Plume” emitted from industrial stacks, if it installed a wet FGD. The “White Plumes” have being attracted great public interest due to their possible negative effects on climate and health risks.

This study firstly reports characteristics of PMs in the “White Plumes” based on measurement at three CFPPs equipped with limestone-gypsum or seawater FGDs. Mass concentrations of water soluble ions (WSIs) in PM samples collected at wet FGD outlets were about 70-90% higher than that collected at the FGD inlets. Highest values were observed for PMs collected in the “White Plumes”. The relative percentage of sulfate ions (SO42-) in total WSIs were about 27%, 54%, and 64% in the three locations, respectively, while relative percentage for ammonia ions (NH4+) were about 11%, 16% and 16%, respectively. Droplets collected in the “White Plumes” showed acidity with a pH in the range of 2 ~ 4 and high WSI concentrations of about 3 ppb. The relative percentage of SO42- and NH4+ in total WSIs were about 63% and 18%, respectively. The increased values of SO42- and NH4+ in plumes are probably due to the condensation of SO2/SO3 and NH3 (slipped from denitration systems), since the temperature of flue gas in stacks (about 25 oC and 50 oC for seawater and limestone-gypsum FGDs, respectively) is generally higher than that of ambient air.

These condensable species, including H2O, SO2/SO3, NH3, and VOCs, can condense on existing PMs via heterogeneous nucleation. The results indicate that reported results in previous publications (obtained in stacks) commonly under-estimate the primary PMs emitted from CFPPs equipped with wet FGDs, especially SO42- and NH4+ concentrations. These experimental findings improve the basic understanding of potential climate and health effects of the “White Plumes”.

7AC.7

Daytime and Night-time Atmospheric Aging of Emissions from Combustion Related Sources by Electrospray Ionization Time-of-Flight Mass Spectrometry (EESI-TOF) in a Smog Chamber. AMELIE BERTRAND, Bin Yuan, Giulia Stefenelli, Yandong Tong, Lu Qi, Liwei Wang, Felipe Lopez-Hilfiker, Sepideh Esmaeilirad, Urs Baltensperger, Imad El Haddad, Jay G. Slowik, Andre S.H. Prévôt, *Paul Scherrer Institute*

Combustion processes are predominant sources of organic aerosol (OA). Several studies have reported their significant contribution to the ambient OA burden. In Europe, biomass burning often accounts for 30 – 50 % of the OA total concentration, while in Asia, coal combustion has been reported to account as up to 30 % of the OA total concentration. The contribution of these sources to the secondary fraction remain however largely uncertain. Due to the complex transformation of the emissions occurring over time in the atmosphere, source apportionment studies can fail to properly distinguish between the different origins of the secondary fraction.

To solve this hurdle, new instruments capable of providing a more extensive knowledge of the chemical composition of the OA at the molecular level and with a high time resolution are necessary. The Paul Scherrer Institute (PSI) has recently developed such an instrument: the extractive electrospray ionization time-of-flight mass spectrometer (EESI-TOF). The EESI-TOF enables real-time chemical analysis of atmospheric particles without thermal decomposition or ionization-induced fragmentation.

Here, we present results of the coupling of the EESI-TOF to a smog chamber to study the evolution during atmospheric aging of the chemical fingerprint of coal and biomass burning emissions generated with residential appliances. Experiments were conducted in the 7m3 atmospheric chamber (Teflon, 20 °C) of PSI. Emissions were oxidized during 4 - 5 hours under a variety of conditions (NO3 and OH chemistry) to simulate atmospheric aging both during the day and at night. A High Resolution – Time of Flight – Aerosol Mass Spectrometer (HR-TOF-AMS) and an Aethalometer AE33 were installed alongside EESI to provide real-time analysis of the bulk chemical composition of the particulate phase, including the non-refractory material and the black carbon. A Proton Transfer Reaction – Time of Flight – Mass Spectrometer (PTR-TOF-MS) was installed to monitor the volatile organic compounds.

We look into the modification of the chemical fingerprint during aging. With EESI we highlight the differences between fresh and aged, OH, and NO3 chemistry profiles, and compare with what is known of HR-TOF-AMS studies. We show time series of specific ions susceptible to serve as tracers for fresh biomass burning and coal combustion emissions, and secondary fraction. And finally we further investigate the evolution of certain of these compounds in the chamber in lights of what is known regarding their volatility and partitioning.

Understanding the Selective Transfer of Carbohydrates from the Ocean to Sea Spray Aerosol. ELIAS HASENECZ, Hansol Lee, Alexei Tivanski, Elizabeth Stone, *University of Iowa*

The ocean is a globally important source of atmospheric aerosols whose composition and properties are both climate relevant and under-examined. These properties, such as radiative forcing and cloud condensation nuclei activity, are influenced by the diversity of chemicals found in ocean derived aerosol. Surface active species are enriched at the ocean surface in the sea surface microlayer (SSML) and are selectively transferred to sea spray aerosol (SSA) via bubble bursting. Among organic matter enriched in SSA are carbohydrates, or saccharides, that primarily originate from biological sources and can comprise a significant portion of SSA organic mass. The selective transfer of a chemical species is facilitated by their properties and surroundings—for example, carboxylic acids are selectively transferred due to increasing surface activity, which is illuminated by decreases in the surface tension of the water interface. Determining the physicochemical processes that drive selective transfer of saccharides will ultimately improve our understanding of SSA composition and resultant globally relevant properties.

In this study, SSAs were produced with granular glass frit bubblers to determine how increasing the number of saccharide monomer units affects their transfer from bulk seawater to SSA. Sub-surface (bulk), SSML and SSA samples were collected using a 5 stage cascade impactor and analyzed for saccharides and ions via high performance ion exchange chromatography with pulsed amperometry and conductivity detection, respectively. Enrichment factors (EF) were calculated by dividing the saccharide-to-sodium ratio in the SSML or SSA by this ratio in bulk solution. To correlate our chemical speciation measurements to changes in physicochemical properties, solution surface tension was also measured using a force tensiometer. Saccharide monomers through hexamers showed no enrichment (EF = 1), which is consistent with no change in surface tension (73.5 ± 0.3 mN/m) and confirms these species are neither surface active nor enriched in the SSML or SSA. However, alginate, an acidic polysaccharide prevalent in seaweed, shows small enrichment (1.6 ± 0.2) in the smallest aerosol size fraction (Nevertheless, the small polysaccharide enrichment shown here is one to five orders of magnitude smaller than studies containing natural seawater and/or microbes, suggesting surface activity alone is not the main driving force for saccharide transfer. For future studies, microgels that are ubiquitous in the ocean, saccharide-rich, positively buoyant and enriched in SSA, will be studied for their capability to selectively transfer saccharides to SSA.

Environmental Factors Affecting Humic-like Substance Production in Photoreactions of Polycyclic Aromatic Hydrocarbons. JOHN HAYNES, Keith Miller, Brian Majestic, *University of Denver*

Humic-like substances (HULIS) are a class of light absorbing compounds and are present in the atmosphere as a collective of organic species, each containing significant aromatic and carboxylic acid character. They are found to be a major component of brown carbon and are connected with radiative forcing in the atmosphere. Aerosolized HULIS are consistently correlated with reactive oxygen species and soluble metals, and as such, they are implicated with respiratory problems, oxidative stress, and the production of phytoplankton in marine systems. Polycyclic aromatic hydrocarbons (PAH) and HULIS are commonly observed in particles sourced from pyrogenic processes, e.g. biomass burning and vehicle exhaust. PAH are produced by the inefficient burning of organic fuels and display extended lifetimes in the atmosphere. These aromatics are toxic to human health and many structures are considered highly carcinogenic. PAH have many atmospheric reaction pathways - one recently discovered endpoint is the formation of HULIS.

This bench study evaluates the impact of environmental changes on HULIS production by oxidation of suspensions of PAH with exposure to sunlight using several different matrix environments. The long range transport of PAH lend themselves to extended exposures to sunlight and reactive environments potentially producing branched and oxidized PAH products (oxPAH) which then act as intermediates for more complex structures, e.g. HULIS. This extended reactive exposure may be affected by changing cloud water environments, including buffer systems, dust entrainment, and soluble metals. Environmental PAH and HULIS are correlated with reactive oxygen species in cloud water and aerosolized particles. Atmospheric aromatics may incorporate ultraviolet radiation with redox reactions of buffered systems or bioavailable metals as photo-Fenton catalysts in an electron transfer interaction with elemental oxygen or water molecules to produce radicals, such as superoxide or hydroxyl radicals. These oxyradicals are highly reactive agents and may initiate several oxidizing pathways, resulting in the further production of HULIS via oxPAH. The introduction of environmental deviations may enhance or inhibit this production by favoring specific or new reaction pathways.

Reaction conditions use simulated sunlight introduced to varying PAH reagent and matrix composition, oxidizing agents, and temperature over 16 hours. Analysis of bulk products are performed using UV-vis, HPLC, and GCMS - used to define the spectroscopic properties and structure of these products. Solid phase extractions of HULIS material are analyzed by GCMS and ATR-FTIR. Initial reaction data include significant differences between dissolved and saturated PAH solutions, as well as changes in the production of oxPAH between soluble ferrous and ferric ion interactions with PAH. Comparison between systems are based on UV-vis analysis and the growth of new HPLC peaks during and following light exposure periods, which monitor the character and production of several new species. Continuous decays within the UV-vis chromatographic spectra and arrays of several products are observed for samples with soil and with dissolved ferric ions and are emblematic of HULIS materials. Comparing these products with strong differences in product data for reactions using dissolved PAH or spikes with ferrous ion are observed and are of particular interest. Evaluating the formation of products from dissolved and suspended PAH solutions with photo-reactions conducted with soluble metals, cloud buffer, and suspended soil allows for the determination of specific reaction mechanisms. A higher understanding of the creation of HULIS in atmospheric conditions will greatly aid in predictive models for air quality and human health downwind of pollution sources.

Effects of Criegee Intermediate Scavenger on Secondary Organic Aerosol Formation during α-pinene Ozonolysis. KEI SATO, Shinichi Enami, Sathiyamurthi Ramasamy, Satoshi Inomata, Takashi Imamura, *National Institute for Environmental Studies, Japan*

Criegee intermediates (CI) might contribute to formation of low-volatility organic compounds such as dimers in the atmosphere. We used a laboratory environmental chamber to investigate the effects of CI scavengers on secondary organic aerosol (SOA) formation from α-pinene ozonolysis in the presence of OH radical scavenger. We used formic acid and heptanoic acid as the CI scavengers, and used carbon monoxide as the OH radical scavenger. Experiments were conducted under dry conditions (RH < 0.1%). Gaseous compounds were measured by FT-IR, and the chemical composition of SOA was measured by AMS. The SOA mass concentrations measured after the consumption of 0.1-ppm α-pinene in the experiments with heptanoic acid (262–275 μg m-3) were higher than those measured with formic acid (189–196 μg m-3) and without a CI scavenger (202–216 μg m-3). The O:C ratios measured for SOA in experiments with heptanoic acid (0.27–0.29) were lower than those measured with formic acid (0.31–0.36) and without CI scavenger (0.30–0.35). We also studied the addition effect of ammonium sulfate seed particles. Similar results were obtained in the presence of seed particles, but the SOA concentrations measured with seed particles are slightly higher than those measured without seed particles. The CIs formed from α-pinene ozonolysis react not only with α-pinene oxidation products but also heptanoic acid. The reactions of the CIs with heptanoic acid would result in formation of the SOA with O:C ratios lower than those formed during α-pinene ozonolysis.

The Predicted Impact of Organic Coatings on Isoprene-Derived Secondary Organic Aerosol Formation. WILLIAM VIZUETE, Mutian Ma, Yue Zhang, Sri Hapsari Budisulistiorini, Havala Pye, Jason Surratt, Yuzhi Chen, Ryan Schmedding, Sarah Farrell, *University of North Carolina at Chapel Hill*

Fine particulate matter (PM2.5) is known to have an adverse impact on public health and is an important climate forcer. Secondary organic aerosol (SOA) contributes to PM2.5 and the multiphase reactions between gas- and particle-phase constituents is an important source. Aerosol-phase state is thought to influence the reactive uptake of gas-phase precursors to aerosol particles by altering diffusion rates within particles. Current air quality models (AQM), however, do not include this feature. This work examines the predicted impact of organic coatings on the formation of SOA from the acid-catalyzed multiphase reactions of isoprene epoxydiols (IEPOX). New experimental studies have provided a systematic quantification of the reactive uptake coefficient (γ) of trans-β-isoprene epoxydiol (trans-β-IEPOX), the predominant IEPOX isomer, onto acidic sulfate particles with varying organic coatings. In some experiments the uptake coefficient was reduced by half of the original value when coatings were present. This new experimental data, and published kinetic rates, now allow for examination of constrains on critical parameters needed to simulate coating effects on reactive uptake. This work developed a 0-dimensional box model that incorporated the latest kinetic data that accounts for coating influences. Meteorological inputs and gas phase concentration data were provided from field measurements at the Look Rock, Tennessee (LRK) ground site during the 2013 Southern Oxidant and Aerosol Study (SOAS). The LRK site also provided particle-phase chemical data of IEPOX-derived organosulfates and 2-methyltetrols that was used for model performance evaluations.

Including a coating influence in the reactive uptake algorithm reduced predicted IEPOX-derived SOA on average by 31%. One critical parameter in the model algorithm was the inorganic Henry's Law coefficient (H), with a range of reported values from 2.7 6 M/atm to 4.0 8 M/atm. Sensitivity simulations from this work found that H had the greatest impact on predictions when a 10-fold increase led to 8-fold increase in SOA concentrations. The organic diffusion coefficient (Dorg) and organic Henry's Law coefficient (Horg) were also found to be a critical parameter. For these simulations, the reported 0.3 M/atm was used for Horg. In the literature Dorg has been derived as a function of relative humidity (RH) either from experimental measurements of IEPOX uptake on -pinene coated sulfate aerosols, or estimates from viscosity data of -pinene SOA. In these model runs when the Dorg is , IEPOX uptake was completely inhibited and when Dorg reached organic coatings had no effect. Using the LRK filter data, and published range of parameter values, a simulation was completed that produced the best model performance where the empirically derived Dorg from -pinene coated aerosols was used with a H of 8.0 7 M/atm and Horg of 0.3 M/atm. This simulation increased SOA concentrations improving the normalized mean bias to -24.7%.

These results suggest that the organic coating layer could have significant impact on the IEPOX-derived SOA formation and should be considered in AQMs. This work relied on organic diffusion coefficients derived from our previous -pinene SOA experiments, and thus, only represents one possible type of organic coatings in the atmosphere. Other organic coatings, such as those derived from anthropogenic and other biogenic sources (including isoprene itself) could have a different impact on the acid-catalyzed reactive uptake of IEPOX. Furthermore, part of the Dorg used in this work were derived with flow tube experiment data occurring only under RH conditions between 15-50% while the Dorg for higher RH are based on viscosity data and experimental extrapolation. Further experimental studies are needed to constrain these parameters in >50% RH environments.

7AC.12

Impact of Ammonium Nitrate Aerosol Formation on Ozone Production in Urban and Rural New York State. MATTHEW NINNEMAN, Sarah Lu, Pius Lee, Jeffery McQueen, James Schwab, *University at Albany, SUNY*

The nighttime deposition of ammonium nitrate aerosol (NH_4NO_3) onto surfaces is an important oxides of nitrogen (NO_x) removal pathway, which affects next-day photochemical ozone (O_3) production. Prior studies have mainly examined this phenomenon in either urban or rural environments. However, these studies have not compared the impact of NH_4NO_3 formation on O_3 production in urban versus rural locations. To address this research gap, this study used continuous NH_4NO_3, ammonia (NH_3), nitric acid (HNO_3), NO_x, and O_3 measurements taken in one urban location and one rural location in New York State (NYS) beginning in mid-2016. In addition, photochemical ozone production rates (P_{O3}) and concentrations of dinitrogen pentoxide (N_2O_5), water vapor (H_2O), nitrous acid (HONO) and gas-phase nitrate (NO_3) are determined for both sites using an air quality model. The urban and rural locations of interest were Queens College (QC) in Flushing, New York (NY), and Pinnacle State Park (PSP) in Addison, NY, respectively. The effect of NH_4NO_3 formation and deposition on next-day photochemical O_3 production differs at QC and PSP. This may be due in part to (1) differences in modeled N_2O_5 and NO_3 concentrations and measured NH_3, HNO_3, and NO_x concentrations, (2) differences in NO_x-sensitive versus NO_x-saturated environments, and (3) differences in the extent of poorly characterized NO_x sources from surface-enhanced re-noxification, all of which are explored in this study.

Mixing State of Oxalic Acid Containing Particles in the Rural Area of Pearl River Delta, China. CHUNLEI CHENG, Mei Li, Chak K. Chan, Haijie Tong, Zhen Zhou, *Jinan University*

The formation of oxalic acid and its mixing state in atmospheric particulate matter (PM) were studied using a single particle aerosol mass spectrometer (SPAMS) in the summer and winter of 2014 in Heshan, a supersite in the rural area of the Pearl River Delta (PRD) region in China. Oxalic acid-containing particles accounted for 2.5% and 2.7% in total detected ambient particles in summer and winter, respectively. Oxalic acid was measured in particles classified as elemental carbon (EC), organic carbon (OC), elemental and organic carbon (ECOC), biomass burning (BB), heavy metal (HM), secondary (Sec), sodium-potassium (NaK) and dust. Oxalic acid was found predominantly mixing with sulfate and nitrate during the whole sampling period, likely due to aqueous phase reactions. In summer, oxalic acid-containing particle number and ozone concentration followed a very similar trend, which may reflect the significant contribution of photochemical reactions to oxalic acid formation. The HM type particles were the most abundant oxalic acid particles in summer and the diurnal variations of peak area of iron and oxalic acid show opposite trends, which suggests a possible loss of oxalic acid through the photolysis of iron oxalato complexes during the strong photochemical activity period. In wintertime, carbonaceous type particles contained a substantial amount of oxalic acid as well as abundant carbon clusters and biomass burning markers. The general existence of nitric acid in oxalic acid-containing particles indicates an acidic environment during the formation process of oxalic acid. The peak areas of nitrate, sulfate and oxalic had similar temporal change in the carbonaceous type oxalic acid particles, and the organosulfate-containing oxalic acid particles well correlated with total oxalic acid particles during the episode, which suggests the formation of oxalic acid is closely associated with the oxidation of organic precursors in aqueous phase.

Fast Heterogeneous N2O5 Uptake and ClNO2 Production in Summer in Urban Beijing, China. WEI ZHOU, Jian Zhao, Bin Ouyang, Asan Bacak, Conghui Xie, Qingqing Wang, Junfeng Wang, Yuying Wang, Wei Du, Weiqi Xu, Archit Mehra, Stephen Worrall, Xinlei Ge, Penglin Ye, James Lee, Hugh Coe, Roderic Jones, Pingqing Fu, Zifa Wang, Douglas Worsnop, Yele Sun, *Institute of Atmospheric Physics*

The heterogeneous hydrolysis of dinitrogen pentoxide (N_2O_5) has a significant impact on nocturnal particulate nitrate formation and photochemistry on the secondary day through the photolysis of nitryl chloride ($ClNO_2$), yet their roles and processes in the highly polluted areas remain less understood. Here we present the measurements of gas-phase N_2O_5 and $ClNO_2$ by a high-resolution time-of-flight chemical ionization mass spectrometer during the Air Pollution and Human Health (APHH) campaign to investigate the nocturnal chemistry in summer in urban Beijing, China. N_2O_5 and $ClNO_2$ show large day-to-day variations that are closely related to their precursors (i.e., O_3 and NO_x). High reactivity of N_2O_5 with $\tau(N_2O_5)^{-1}$ ranging from 0.20×10^{-2} to 1.46×10^{-2} s^{-1} suggests active nocturnal chemistry and a large nocturnal nitrate formation potential via N_2O_5 heterogeneous uptake. We also observed high $ClNO_2/N_2O_5$ ratios, likely due to the correspondingly high $ClNO_2$ production rate under sufficient chloride in Beijing. The N_2O_5 uptake coefficients estimated from the product formation rates of $ClNO_2$ and particulate nitrate are in the range of 0.017-0.190, corresponding to the direct N_2O_5 loss rates of 0.00044-0.0034 s^{-1}. Further analysis indicate that the fast N_2O_5 loss in the nocturnal boundary layer in urban Beijing is mainly attributed to the indirect NO_3 loss pathway, for example, through the reactions with volatile organic compounds and NO, while the contribution of heterogeneous uptake of N_2O_5 is small (7-33%). We also observed high $ClNO_2$ yields ranging from 0.10 to 0.35 which might have important implications for air quality by affecting the nitrate and ozone formation.

Multivariate Statistical Analysis Methods as a Tool to Study Complex Mass Spectrometry Data Sets. SINI ISOKÄÄNTÄ, Eetu Kari, Angela Buchholz, Annele Virtanen, Santtu Mikkonen, *University of Eastern Finland*

Mass spectrometer measurements produce complex data with a large number of variables. In this work, we used different statistical dimension reduction techniques to compress the information from the data to a small number of factors, which can be further interpreted. Different variations of Positive Matrix Factorization (PMF), Exploratory Factor Analysis (EFA) and Principal Component Analysis (PCA) were applied to multivariate car exhaust emission data measured by proton-transfer-reaction time-of-flight mass spectrometry (PTR-ToF-MS). In the experiments, the diluted gasoline car exhaust was fed into an environmental chamber, and it was further photo-oxidized to clarify the possible reactions of gasoline car exhaust with OH-radicals in the atmosphere.

This work showed that different statistical methods produced similar results, but EFA created factors with the most plausible physical interpretation for the experiments. EFA separated PTR-ToF-MS measured car exhaust data into four different factors: Feeding factor, secondary organic aerosol (SOA) precursor factor, reaction side product factor, and reaction product factor.

The benefit of EFA and PCA compared to PMF is that these methods scale the variables and only the relative changes in concentrations are taken into account. Generally, this allows these methods to discover very small changes in the time series of the variables even if the concentrations are low. The advantage of PMF that PMF calculates the results in data units whereas EFA/PMF results have arbitrary units. In our work, however, we calculated the EFA/PCA factors also in the data units by multiplying the original data with the loading values (i.e. contribution of a variable to a factor) acquired from EFA/PCA. This allowed us to compare the factor time series from different methods reliably. This work demonstrated that all statistical methods tested offered valuable tools for complex data set analysis. Particularly, EFA was useful in this specific case because it identified the most interpretable factors from the experiments.

Molecular Diffusion Limitations Coupled with Aerosol Aging Initiated by Iron Citrate Photochemistry. PABLO CORRAL ARROYO, Peter Aaron Alpert, Jing Dou, Beiping Luo, Ulrich Krieger, Markus Ammann, *Paul Scherrer Institut*

Physical and chemical transformations that change the properties of atmospheric particles are known as aerosol aging. Understanding of these is essential to evaluate their impact on climate, air quality and health. Photochemistry may start aging processes by the presence of chromophores in aerosol particles that act as photocatalysts inducing oxidation of non-absorbing molecules [1]. Iron (Fe(III)) carboxylate complexes absorb light below about 500 nm followed by ligand to metal charge transfer (LMCT), the reduction of iron to Fe(II) and oxidation of the carboxylate ligands, a process that is recognized as an important sink of organic acids in the troposphere [2]. We investigate the feedbacks between these photocatalytic processes and molecular diffusion within aerosol particles. To achieve this scope, iron oxidation within mixed iron citrate and citric acid (1:1 molar ratio) particles is spatially mapped before and after irradiation with UV light (370 nm) using scanning transmission X-ray microscopy with near edge X-ray absorption fine structure spectroscopy (STXM/NEXAFS). This yields 2D-projected Fe(II) and Fe(III) fractions with 35x35 nm resolution. We observed gradients in the composition of single aerosol particles which indicates oxygen diffusion limitation. Additionally, we measure the release of HO_2 radicals and volatile organic compounds (VOCs) to the gas phase when films loaded with iron citrate and citric acid in Coated Wall Flow Tube (CWFT) are irradiated with light. The nonvolatile compounds produced after irradiation are analyzed by HPLC-MS. Finally, we present a numerical photochemical and molecular diffusion model to explain our results. We have found that particles can be devoid of oxygen due to reacto-diffusive limitation and thus, maintain reduced particle cores despite being surrounded to the oxygen rich atmosphere. This is counter to a typical concept that oxygen saturates atmospheric aerosol.

A Combination of a Cavity Ring Down Spectrometer and an Electrodynamic Quadrupole to Retrieve Physical and Optical Constants from Single Trapped Particles. ANTONIO VALENZUELA, Jonathan P. Reid, Allen E. Haddrell, Bryan R. Bzdek, Rose Willoughby, Andrew J. Orr-Ewing, *University of Bristol*

The rapid changes in climate observed during recent decades have important social and economic impacts on both global and regional scales that have brought climate change into the spotlight worldwide. According to the Fifth Assessment Report (AR5) of the last Intergovernmental Panel on Climate Change (IPCC) in 2013, atmospheric aerosol produces a net cooling effect of the Earth's climate. However, an accurate estimate of this cooling is extremely difficult because of the large uncertainty on the estimation of the aerosol radiative forcing (RF), where the largest uncertainty in RF is due to uncertainties in understanding aerosol properties. Reduction of these uncertainties requires improved methods of laboratory determination of the optical properties of aerosol particles and their change with ambient relative humidity. Cavity ring-down spectroscopy (CRDS) has been proven to be a sensitive tool for measuring the absolute extinction cross-sections for single aerosol particles with high precision by combining optical confinement and levitation of a particle with CRDS (1). Studies on single particles, confined within optical or electrodynamic traps, provide precise measurements of aerosol refractive indices, hygroscopic growth, evaporation of semivolatile components, and other properties of importance for their atmospheric behavior. However, overall, these studies have been focused on characterizing optical and physical properties of non-absorbing aerosols. In this sense, we have designed and built an Electrodynamic Quadrupole (EQ) trap to confine and levitate a wide range of different single aerosol particles even absorbing particles. We present a new experimental approach which uses a combination of CRDS and an EQ trap which will allow the measurements of absolute light extinction cross-sections and optical constants and their dependence on environmental conditions over an extended time frame for single aerosol particles. We expect to extend previous analysis centered on non-absorbing aerosols to the more challenging case of absorbing aerosols allowing direct determination of the change in physical and optical properties of micrometer-sized aerosol particles over time. We will demonstrate that such a single particle technique leads to a significant reduction in the uncertainty in the complex refractive index, reducing, for example, the uncertainty in the real part to ±0.3 % and retrieving a more precise imaginary part for absorbing aerosols. We will report retrievals of optical properties of aerosol spanning from simple mixtures of organic components through to samples of laboratory surrogates of secondary organic aerosol.

Radiative Absorption by Light Absorbing Carbon: Uncertainty, Seasonal and Spatial Variation in a Typical Polluted City in Yangtze River Delta. DONG CHEN, Yu Zhao, Ritao Lyu, Jie Zhang, *Nanjing University*

One of the major challenges in understanding radiative forcing by aerosols is to accurately monitor and assess the light absorbing components and their contributions to climate forcing in the present-day atmosphere. In this study, the optical properties of light absorbing carbon (LAC) in aerosols, including its temporal and spatial variations were studied at suburban (NJU), urban (PAES) and industrial (NUIST) sites in Nanjing, a typical polluted city in Yangtze River Delta (YRD). It was found that the application of constant values for multiple scattering factor could not well represent the actual absorption characteristics of aerosols in Nanjing. The relative deviation between calculated and measured absorption coefficients of BC was up to 56 ± 34%. An improved method that applied local multiple scattering correction factors could reduce the uncertainty to less than 5%. Distinct seasonal variation exhibited in the mass absorption efficiency ($MAE_{BrC,365}$) of brown carbon (BrC) at NJU. BrC from secondary sources had a stronger absorption ability than that from primary emissions such as diesel vehicles in winter. $MAE_{BrC,365}$ in autumn when the SOA precursors were dominated by anthropogenic volatile organic compounds (VOCs) was 1.9 times higher than that in summer when biogenic VOCs were the main secondary organic aerosol (SOA) precursors. At industrial site, BrC was mainly formed by aged secondary organic carbon (SOC) and had a stronger light absorbing ability than that at other two sites. The results of simultaneous observation at NJU and PAES indicated that formation of fresh BrC enhanced the optical absorption of BC but reduced that of BrC. This study indicates the necessity of measurement of local multiple scattering factor for evaluation of BC absorption and implies possible ways to alleviate the light absorption effect of LAC.

7AC.19

Chemical Composition Changes during Secondary Organic Aerosol Particle Evaporation. ANGELA BUCHHOLZ, Arttu Ylisirniö, Claudia Mohr, Celia Faiola, Eetu Kari, Andrew Lambe, Zijun Li, Aki Pajunoja, Sergey Nizkorodov, Siegfried Schobesberger, Douglas Worsnop, Taina Yli-Juuti, Annele Virtanen, *University of Eastern Finland*

The partitioning of compounds between gas and particle phase can be described with the Volatility Basis Set (VBS), which group them by their saturation vapor pressure. In previous studies, slower evaporation than expected from VBS distributions was observed for α-pinene particles at dry conditions. This could be caused by physical limitations or by chemical processes in the particle phase. It is therefore important to study the changes of the chemical composition of particles during evaporation to gain insights into the processes governing particle evaporation.

We investigated Secondary Organic Aerosol (SOA) from photooxidation of a-pinene with three different O:C ratios (0.55, 0.70, and 0.95). Monodisperse particles were fed into a Residence Time Chamber (RTC), which was at 0%, 40%, or 80% RH, to study evaporation times up to 10 h. The particle size was monitored and the chemical composition of the particles was studied with an Aerosol Mass Spectrometer and a Filter Inlet for Gases and AEROsols coupled with a Chemical Ionization Time-of-Flight Mass Spectrometer (FIGAERO-CIMS).

Particle evaporation was enhanced at higher RH with little change between 40% and 80%. Evaporation strongly depended on the initial particle composition, with lower volatility and a shift towards higher desorption temperatures in the FIGAERO thermograms (total ion count vs desorption temperature) for particles with higher O:C ratios.

Positive Matrix Factorization (PMF) was applied to the thermogram mass spectra data. The identified factors represent volatility classes which can be compared qualitatively to VBS distributions derived from other sources. Four to seven PMF factors were needed to reproduce the measured thermograms. Larger contributions of the low volatility classes were observed with increasing average O:C ratios. As expected from the thermograms, the residual particles after RTC evaporation contained a higher contribution of low volatility classes, but contrary to the expectation the average O:C ratio of the particles did not change with evaporation.

These results have important implications on our understanding of the fate of particles as they are transported and undergo further oxidation in the atmosphere. Higher oxidation levels and dry conditions make particles more resilient against evaporation and this need to be considered when predicting the climate effect of SOA with an equilibrium gas-particle partitioning model.

PRAPPE: Influence of Iron on the Photoaging of Particulate Matter in the Environment. FRANK LERESCHE, Joseph Salazar, David Pfotenhauer, Michael Hannigan, Brian Majestic, Fernando Rosario-Ortiz, *University of Colorado, Boulder*

Particulate Matter ($PM_{2.5}$) are produced by a variety of processes (e.g. from anthropogenic activities such as road emissions but are also emitted from natural sources) and are a particularly important research topic due to their detrimental impacts on human health. We present here investigations on the photoaging of these $PM_{2.5}$ in the aqueous phase and particularly on the influence of iron on the generation of hydroxyl radicals ($OH^•$) that are one of the major species driving to the photoaging of the $PM_{2.5}$. $OH^•$ being produced in PM extracts under irradiation through the Photo-Fenton reaction, nitrate photolysis and from the dissolved organic matter.

A sampling campaign called PRAPPE (Platte River Air Pollution and Photochemistry Experiment) investigating the properties of $PM_{2.5}$ coming from an urban, a rural and a mixed urban-rural site was done in the Denver area, Colorado. Characterization of the Iron speciation in the different sites as well as the measure of the total and soluble metals was the subject of another abstract. The focus of this abstract is on the photoaging mechanisms that drive the fate of $PM_{2.5}$ in aqueous phase and on the influence of Iron on the photoaging. The optical properties, such as the absorbance and fluorescence, and the capability of the $PM_{2.5}$ aqueous extracts to generate hydroxyl radical under simulated sunlight were investigated. Furthermore, the effects of solar irradiation were further explored by submitting the $PM_{2.5}$ extracts to simulated sunlight, artificially photoaging them. The observed light absorbance capacity was higher in the urban site than in the rural one and it was observed that the decrease in light absorbance properties during photoirradiation was correlated with the iron content of the extracts. The observations correspond to a scenario were the $PM_{2.5}$ are mostly produced in the urban site and are transported to the rural one, with a mean age of the $PM_{2.5}$ higher in the rural site.

This work should help to understand the parameters that influence the photoaging of $PM_{2.5}$ in the atmosphere, as well as the influence of trace elements on this process.

7AC.22

The Condensed-phase Ozonolysis of an Unsaturated Triglyceride: Reaction Kinetics and Products. ZILIN ZHOU, Shouming Zhou, Jonathan Abbatt, *University of Toronto, Canada*

Ozone plays an important role in both outdoor and indoor chemistry. It is well known that the gas-phase ozone oxidation of gas-phase alkenes, such as terpenes, leads to the formation of oxidized products, such as carbonyls and Criegee intermediates. However, despite the well-studied gas-phase mechanism, the fate of condensed-phase ozonolysis on surfaces and in aerosol particles is still not fully understood. In this study, a common component seen in most cooking oils, triolein (a triglyceride arising from glycerol and oleic acid) was oxidized by ozone on a surface. The rapid decay of triolein was observed, accompanied by the formation of secondary ozonides and a series of oxygenated compounds (acids and aldehydes). The uptake coefficient of ozone will be reported. To do this work, a sensitive technique using high-performance liquid chromatography/electrospray ionization mass spectrometry (HPLC-ESI-MS) was developed for the quantitative analysis of triolein and its oxidized products. In particular, the reactivity of the secondary ozonide products was also studied using this analytical method, under ambient conditions of light and relative humidity (RH). The results indicate that the condensed-phase oxidative chemistry of triglycerides is complex, driven primarily by the resulting Criegee intermediates. The environmental implications for this chemistry will be discussed. In particular, trigylcerides are an important component of cooking organic aerosol, and they will be deposited on indoor surfaces close to where cooking is performed.

Characterization of Aerosol Composition, Aerosol Acidity and Organic Acid Partitioning at an Agriculture-intensive Rural Southeastern U.S. Site. Theodora Nah, Hongyu Guo, Amy P. Sullivan, Yunle Chen, David Tanner, Athanasios Nenes, Armistead G Russell, Nga Lee Ng, Greg Huey, RODNEY J. WEBER, *Georgia Institute of Technology*

U.S. air quality regulations have led to decreased emissions in traditional air pollutants such as CO, NOx and SO2. In contrast, NH3 emissions have remained essentially unchanged, and may even increase in the future due to increased agricultural activities from a growing world population. These emission trends point to an increasingly important role that NH3 plays in atmospheric aerosol chemistry. We present real-time aerosol and trace gas measurements from a field study conducted in an agricultural-intensive region in Georgia during the fall of 2016. The goal was to understand how NH3 affects particle acidity and SOA formation via the gas-particle partitioning of semi-volatile inorganic and organic compounds. Particle pH and water were determined using the ISORROPIA-II thermodynamic model and validated by comparing predicted inorganic HNO3-NO3- and NH3-NH4+ gas-particle partitioning ratios with measured values. Our results showed that despite the high NH3 concentrations at the field site (study average 8.1 ± 5.2 ppb), PM1 are highly acidic with pH values ranging from 0.5 to 3.7 and a study-averaged pH of 2.1 ± 0.6 due to pH buffering by NH3 partitioning between the gas and particle phases. PM1 pH varied by approximately 1.4 units throughout the day. Gas-phase organic acids as large as C5 were detected at the site. Ambient concentrations of gas-phase organic acids ranged from a few parts per trillion by volume to several parts per billion by volume, with the largest concentrations observed for formic and acetic acids. Measured particulate organic acids comprised 6 % of the total organic aerosol mass concentration, with significant contributions from oxalic and succinic acids. The fractions of formic, acetic and oxalic acids present in the particle phase increased with PM1 pH. Measured formic, acetic and oxalic acid gas-particle partitioning ratios were also compared to their corresponding analytical predictions, which were calculated based on the organic acid's physicochemical properties, ambient temperature, particle water and pH. While the measured oxalic acid gas-particle partitioning ratios (fraction in the particle phase ranged from 39 to 88 % at pH between 1.2 and 3.3) generally agreed with analytical predictions, this was not the case for formic and acetic acids. Possible reasons for these disagreements will be discussed.

7AC.24

N2O5 Reactive Uptake and Chlorine Activation during Nocturnal Processing of Authentic Biomass Burning Aerosol.

LYDIA JAHL, Lexie Goldberger, Joel A. Thornton, Ryan Sullivan, *Carnegie Mellon University*

Nitryl chloride ($ClNO_2$) is a nighttime reservoir of NO_x that is formed from the uptake of dinitrogen pentoxide (N_2O_5) into particles containing chloride. $ClNO_2$ was thought to be formed only in the presence of chloride from sea spray aerosol, but its recent detection in areas far from the ocean has raised the possibility that other unrecognized particulate chloride sources make important contributions to chlorine activation chemistry. $ClNO_2$ is photolyzed each morning to produce the chlorine radical and recycle NO_x, thereby increasing the atmospheric oxidant budget. We recently demonstrated the production of $ClNO_2$ from heterogeneous reactions with $N_2O_5(g)$ under realistic conditions in a smog chamber reactor at Carnegie Mellon University. Iodide adduct chemical ionization mass spectrometry was used to measure gas phase $ClNO_2$ and N_2O_5, while a soot particle aerosol mass spectrometer measured changes in aerosol composition. Upon the addition of ozone to biomass burning smoke, N_2O_5 was consistently formed and $ClNO_2$ was subsequently detected in the gas phase. During experiments at high relative humidity, we observed decreases in particulate chloride and increases in particulate nitrate which we believe are due to acid displacement of HCl(g) by HNO_3 since no additional $ClNO_2$ was produced in the gas phase. The reactive uptake probability of N_2O_5 on authentic biomass burning aerosol and the yield of $ClNO_2$ were determined for the first time using flow tube experiments on smoke from biomass fuels including wiregrass, black needlerush, saw palmetto, and longleaf pine needles. Despite significant differences in aerosol composition, similar low reactive uptake coefficients were determined, in the range of 0.002-0.006. We investigated the controlling role that the aerosol particles' morphology and chloride mixing state play in the reactive uptake of N_2O_5 through single-particle analysis. N_2O_5 reactive uptake and the yield of $ClNO_2$ vs. HNO_3 were parameterized as a function of aerosol composition and mixing state, for incorporation into chemical transport models.

7AC.25

High Abundance of Oxalic Acid in a Rural Atmosphere of Eastern Central India: Influence of Biomass Burning and Photochemical Processing. DHANANJAY KUMAR DESHMUKH, Manas Kanti Deb, Kimitaka Kawamura, Dharmendra Kumar Singh, *Chubu University, Japan*

Organic aerosols (OAs) are abundant in the troposphere and crucial for air quality and climate. The oxidation products of OAs are highly water-soluble and typically contain several functional groups. Fine aerosol samples (PM2.5) were collected at a rural site of eastern central India (Ambikapur: 23.12°N and 83.20°E) during March to June 2017. The samples were analyzed for water-soluble dicarboxylic acids (C2-C12), glyoxylic acid (ωC2), glyoxal (Gly) and methylglyoxal (MeGly) as well as organic carbon (OC), elemental carbon (EC) and water-soluble OC (WSOC). Oxalic acid (C2) was detected as the most abundant species followed by succinic (C4) or malonic (C3) acids. The temporal variability in concentrations of C2 diacid and related compounds was pronounced during the end of March to the middle of April when biomass burning episodes were dominant in eastern central India. The strong correlation of C2 with levoglucosan ($r = 0.91$) suggests that biomass burning was a major source of oxalic acid in eastern central India. Strong correlations of the C2 with saturated diacids (C3-C9: $r = 0.81$-0.96), ωC2 ($r = 0.95$), Gly ($r = 0.92$) and MeGly ($r = 0.80$) suggest their similar sources and formation processes and that oxalic acid in fine aerosols may be secondarily produced from these precursor compounds. The ratios of WSOC to OC (0.52-0.88) and C3 to C4 diacid (0.69-1.30) suggest that water-soluble organic aerosols (WSOAs) were photochemically processed during the campaign. Our results demonstrate that severe biomass burning and photochemical processing enhanced abundances of WSOAs in a rural atmosphere in eastern central India.

7AC.26

In-situ Surface Tension Measurements of Hanging Droplet Aerosol Mimics under Photooxidative Conditions. Thomas Beier, JOSEPH WOO, *Lafayette College*

Oligomeric products of carbonyl-containing volatile organic compounds (CVOCs) have been shown to exhibit surface-active properties in aqueous aerosols, affecting their contributions to indirect radiative forcing effects on the atmosphere. These aerosol-phase oligomeric products are also known to exhibit compositional changes due to photobleaching in UV-irradiated environments. The relative rates of formation and effects of these oxidized compounds may be enhanced in aerosol conditions compared to in bulk phase due to their relatively high surface area, where these surface-active substances are thought to partition. In this study, surface tension and UV/Vis spectrographical data is collected for small (<20uL) hanging-drop aqueous aerosol mimics, which are exposed to controlled gas-phase CVOCs and UV radiation. These droplets act as an intermediate size scale between bulk mimic and aerosol-chamber studies, allowing for direct individual droplet measurement while maintaining a relatively high surface-volume ratio for heterogeneous photochemistry to occur. Observed surface tension and absorbance measurements are compared to Syszkowski-Langmuir and bulk-phase absorbance estimations (respectively) using GAMMA, a 0-dimensional computational box model.

Assessment of the Influence of Cut-Off Shift Due to Particle Hygroscopic Growth on the Analysis of Its Chemical Composition.

YING CHEN, Oliver Wild, Yu Wang, Liang Ran, Monique Teich, Johannes Größ, Lina Wang, Gerald Spindler, Hartmut Herrmann, Dominik van Pinxteren, Gordon McFiggans, Alfred Wiedensohler, *Lancaster Uni. and TROPOS*

Particulate matter is of major concern in the world nowadays, due to its effects on public health and climate. The chemical composition of particles is a crucial factor in these effects. Filter sampling is one of the major ways to measure aerosol compositions. However, the cut-off size for particle sampling shifts in different ambient conditions due to hygroscopic growth. This leads to difficulties in consistent comparisons between measurements under different conditions (spatial and temporal). This problem cannot be easily solved by drying airflow, since there is no efficient way to dry it for a high-volume aerosol sampler; moreover, the drying or heating processes change the gas-particle equilibrium and lead to a loss of semi-volatile compounds (e.g. nitrate and secondary organic aerosol). Here, we propose a method to assess this influence based on κ-Köhler theory (Petters and Kreidenweis, 2007). A global perspective on this influence is reported. This study is important for a consistent analysis of the long-term characteristics and spatial distributions of particle chemical compositions, and brings more confidence to model validation.

To explore the cut-off shift in filter-based particle sampling due to hygroscopic growth, we calculate the aerodynamic diameter of ambient particles based on the hygroscopic growth factor (GF) of size. The GFs are derived from κ-Köhler theory, with consideration of particle composition and size as well as meteorological conditions. The κ value, representing the dependence of particle hygroscopicity on chemical composition, can be estimated with composition measurements following the Zdanovskii-Stokes-Robinson mixing rule and Liu et al. (2014). Here, we adopt the previous reported global distributions of κ value (Pringle et al., 2010), relative humidity (RH, Dai, 2006) and temperature (Willett et al., 2014) to estimate the GF of particles in different sizes. The particle volume size distributions (PVSD) of eight different aerosol types (Whitby, 1978) are used to assess the influence of cut-off shift on chemical analysis.

Generally, European background sites seem to be more greatly influenced by the cut-off shift than those in other continents, with 10-20% in median and may reach 50-60% in some cases when hygroscopic particles present in humid air mass. However, the influence is generally much smaller (less than 7%) at all urban sites, and is negligible for hydrophobic dust particles. Sea salt aerosol (SSA) experiences the largest influence (about 50% in median), resulting from their large size, high hygroscopicity and high RH in marine air masses. A difference of more than 30% in the influence on SSA sampling can be observed between relatively dry and humid conditions. This work highlights importance of considering cut-off shift in chemical analyses when compare between different spatial/temporal conditions.

Size-Resolved Physicochemical Properties of Organic Salt Nanoparticles. Sabrina Chee, Michael Lawler, Kelley Barsanti, Bryan Wong, JAMES SMITH, *University of California, Irvine*

The volatility and hygroscopicity of atomized alkylaminium carboxylate particles have been previously studied in laboratory experiments. However, these properties have not been measured for nanoparticles formed from the acid-base reaction between gas-phase alkylaminium bases and organic acids. To study this, gas-phase acetic acid (CH_3COOH) and dimethylamine (DMA) were introduced into a flow tube reactor to nucleate and grow nanoparticles (defined here as < 50 nm) under dry and elevated relative humidity conditions. A Thermal Desorption Chemical Ionization Mass Spectrometer (TDCIMS) was used to measure the size-resolved chemical composition of the nanoparticles formed, and volatility and hygroscopicity measurements were taken by using Volatility and Hygroscopicity Tandem Differential Mobility Analyzers (H- and V-TDMAs, respectively).

Acid:base ratio measurements from TDCIMS are presented. Size-resolved volatility measurements suggest that dimethylaminium acetate nanoparticles are less volatile than ammonium sulfate nanoparticles of comparable sizes and temperatures. These results are combined with thermodynamic modeling to explore the limits of bulk thermodynamic properties of acids and bases, such as pKa, in determining the size-dependent acid:base ratio of the dimethylaminium acetate nanoparticles formed. The implications of these modeling observations on alkylaminium carboxylate nanoparticle volatility are also discussed.

Physical and Chemical Submicron Aerosols Properties and Their Link to Size-resolved Aerosol Hygroscopicity in Summer/Spring of Seoul, Korea. NAJIN KIM, Minsu Park, Seong Soo Yum, Hye Jung Shin, Jong Sung Park, Joon Young Ahn, *Yonsei University*

Hygroscopic behavior of aerosols are important parameter of climate change and air quality as aerosol hygroscopicity is not only connected to cloud condensation nuclei (CCN) activity but also to the visibility in highly polluted areas. It is widely known that aerosol hygroscopicity is closely related to physical and chemical properties of aerosols. In this study, characteristics of submicron aerosols and their links to aerosol hygroscopicity are examined based on the results of KORUS-AQ (May-June, 2016) and MAPS-Seoul (May-June, 2015) campaigns, which aims at understanding various aspects of air quality problem in Seoul, highly urbanized area in Korea. Size-resolved aerosol hygroscopicity were measured by hygroscopic tandem differential mobility analyzer (HTDMA) and analyzed with data from various instruments for measuring physical and chemical aerosol properties: CPC, SMPS, CCNC, HR-ToF-AMS and MAPP.

Distinct diurnal patterns of size-resolved aerosol hygroscopictiy and mixing state were observed during the measurement periods. In the morning, aerosols are externally mixed with freshly emitted particles by vehicles and existing aged aerosols. Mixing state change occurred in the afternoon when photochemical process is active. Sharply increased hygroscopicity of small particles and O/C ratio were observed in that time. During KORUS-AQ campaign, chemical composition of aerosols varied by sources (inorganic-dominant/ organic-dominant period) and impacted on aerosols hygroscopicity and even CCN spectrum even though aerosol number concentration changed very little. Good agreement with GF-derived κ from HTDMA and AMS-based κ when considering oxidation state and BC mass concentration also implies that hygroscopic properties of aerosols are associated with chemical properties of aerosols as well as physical properties of aerosols. Analysis of aerosol chemical composition with size-resolved aerosol hygroscopicity during NPF events and difference between GF-derived κ and CCN-derived κ will be discussed in the conference.

Aerosol Acidity Measurement Using Colorimetry Coupled with a UV-Visible Micro-spectrometer and Its Application to Measurements of Organosulfates in Ambient Air.

SHIQI SUN, Myoseon Jang, *University of Florida*

Although SO_2 concentration has been reduced in USA for last two decades, the acidic aerosol produced from the oxidation of SO_2 is still an existing problem in many countries (i.e., Asia and South America) who rely on coal for heating and industries. Sulfate significantly contributes to total fine particulate matter, and yet the prediction of aerosol acidity remains inadequate. Atmospheric aerosol acidity influences the health effects of particulates due to metal solubility, and is also a kinetic model parameter that processes acid-catalytic reactions of atmospheric organics and organosulfate formation to increase secondary organic aerosols. Our laboratory's recent research efforts have improved the state-of-the science-art via the development of colorimetry integrated with a Reflectance UV-Visible spectrometer (C-RUV). In this study, a portable C-RUV device in the field is developed using a micro-spectrometer that is self-contained and deployable. The C-RUV technique operates by passing an air sample through a filter infused with an indicator (i.e. metanil yellow), which changes color in response to acidity changes. The optical probe transfers both the source beam from the micro-spectrometer to the filter surface through the optical fiber, and the reflected beam from the filter to the detector in the micro-spectrometer. The proton ($[H^+]$, mol/L of aerosol) measurement by the C-RUV method has been calibrated for inorganic aerosols comprised of ammonium and sulfate under varied humidity conditions using a flow tube. The resulting C-RUV device and the calibration equation are applied to quantify $[H^+]$ in the ambient air. The acidity aerosol can be modulated by both neutralization of sulfuric acid with ammonia and the formation of organosulfate in aerosol. The concentration of organosulfate in aerosol is also estimated by using the difference in proton concentrations obtained from C-RUV and a particle into liquid sampler ion chromatography (PILS-IC) in ambient air. The aerosol acidity measurement using C-RUV device is able to improve the modeling of aerosol formation and the prediction of aerosol hygroscopicity.

Simultaneous Water Uptake and Size-resolved Bounce Measurement of Secondary Organic Aerosols. DEVOUN STEWART, David De Haan, Richard Gardner, *University of San Diego*

The phase change of secondary organic aerosols in the atmosphere is of significant scientific interest because of its effects on climate. The effect of aerosols on climate is closely linked to aerosol interaction with water. Solid aerosols can uptake water under humid conditions, which causes them to liquefy. Under these conditions, the optical properties of aerosols, which depends on its size and phase, will change. The light scattering properties of aerosols increase significantly when particle absorbs water. Since the climate effects of aerosols are closely tied to interactions with water, we developed an instrument capable of simultaneous aerosol water uptake and size-resolved bounce measurements. This instrument uses two SMPS system connected to a MOUDI impactor to simultaneously measure both particle growth and bounce factors at various controlled relative humidity. The size-resolved bounce measurements allow us to determine how much water uptake is required for the aerosol to liquefy. In this presentation, we will present results of the size-resolved phase change and growth factors of different secondary organic aerosols. Our instrument was validated by measuring the growth and bounce factor of ammonium sulfate aerosols.

7AC.32

Temporal Variability of Fine Particle Liquid Water Content over a National Park in Central India. SAMRESH KUMAR, Ramya Sunder Raman, *Indian Institute of Science Education and Research, Bhopal*

Aerosol liquid phase water (ALW) is an important component of ambient aerosols. Water condensed on aerosols promotes heterogeneous chemical reactions along with obscuring the visibility, altering the hydrological cycle and influencing regional climate. It also influences the atmosphere-biosphere interactions, transport, atmospheric processing and fate of trace species. ALW is dependent on relative humidity, temperature, aerosol composition and concentration.

This work focuses on understanding the impacts of relative humidity, temperature, aerosol composition and concentrations on ALW for different time scales. 12 hour integrated samples ($PM_{2.5}$) were collected over a National Park in Central India for two years (2012-2013, N=329; day and night) on multiple filter substrates using co-located Mini-VolTM samplers. Onsite metrological parameters were also recorded using Vaisala WXT-520 sensors. Water soluble inorganic ions in $PM_{2.5}$ were determined using Ion Chromatography while organic and elemental carbon were determined using the DRI Thermal Optical Transmittance/Reflectance analyzer. Inorganic ions along with metrological parameters (relative humidity, temperature) were used to calculate the ALW content. Results of ALW content calculated using the Extended Aerosol Inorganic Model (E-AIM) and κ-Köhler theory (organic particle water) will be presented.

7AC.33

Atmospheric Concentration of Polycyclic Aromatic Hydrocarbons (PAHs) and Nitro- PAHs, Their Temperature Dependence and Gas to Particle Partitioning at a Traffic site in Agra, India.

PUNEET KUMAR VERMA, Dinesh Sah, Rangu Venkata Satish, Neeraj Rastogi, K. Maharaj Kumari, Anita Lakhani, *Dayalbagh Educational Institute, Agra 282005, India*

Sixteen priority and two Nitro-Polycyclic Aromatic Hydrocarbons was measured simultaneously both in the gas and particulate phase between October 2015 to July 2016 in the ambient air of Agra, India. Gas and particulate phase samples were collected using High volume sampler on Poly urethane foam plugs and Quartz micro fiber filter papers respectively. Samples were extracted in a mixture of DCM and n-hexane and further analysed using Gas Chromatograph coupled to a Mass Spectrometer. During the sampling period the average total PAH concentration in particulate phase and gas phase were 3121 ± 308.9 and 1732.5 ± 175.1 ng m^{-3} respectively whereas the concentration of Nitro PAHs was 65.3 ± 16.3 and 24.6 ± 6.55 ng m^{-3} in the particulate phase and gas phase respectively. Gas particle partitioning of PAHs was investigated employing the Junge-Pankow adsorption, K_{OA} Absorption and Dual model. Statistically significant correlation ($p<0.001$) for log Kp vs log $P_{\underline{o}l}$ was obtained for individual PAHs. Temperature dependency of ambient concentration of PAHs was also investigated using Clausius–Clapeyron plots which suggests that concentration of high volatile PAHs is influenced by the temperature. Positive slope of log Kp and 1/T suggest that the density of PAHs (m^3 μg^{-1}) is directly proportional to ambient temperature. In health risk assessment DbA was found as the most carcinogenic and mutagenic as compared to other PAHs followed by BaP.

Key words: Polycyclic Aromatic Hydrocarbons (PAHs), Nitro-PAHs, Junge-Pankow adsorption model, K_{OA} absorption model, Dual model.

7AC.34

New Methods for the Study of the Effects of NOx on SOA Formation. WEIHAN PENG, David R. Cocker III, *University of California, Riverside*

NOx effects are important on SOA formation in atmosphere since both low vapor pressure species formed in peroxide rich (low-NO) conditions and organic nitrate formation in higher NOx environments affect aerosol formation. Current regional air quality models, when considering NOx effects, are guided by results from classic environmental chamber experiments, most of which explore the influences of initial NOx concentration on final SOA formation. During most of these experiments, significant SOA formation does not start until the NO in the system is depleted through oxidation to NO2 and such experiments might have multiple NOx regimes regardless of the absolute amount of NOx injected, so they may miss important SOA formation pathways leading to errors to these models. Therefore, it is important to design new methodologies to study NOx effects at different regimes in environment chamber to provide a more accurate guidance to air quality models. In this study, instead of completing the precursor VOCs and NOx injections before the start of SOA formation like it is in traditional chamber experiments, the timing and method of VOC precursors and NOx are altered in the current work to enhance and simulate the conditions for peroxide and organic nitrate formation. Varied amounts of NOx were injected after the SOA formation commences to explore its effects in peroxide rich environments. Different injection methods including continuous and step-wise injection were conducted to study the instantaneous effects. Additional experiments were performed with precursors VOCs injected after depletion of NO to study NOx effects in low NO conditions.

This study presents experimental observations from the photo-oxidation systems of major anthropogenic VOCs (e.g., aromatics), biogenic monoterpene and poly-aromatic hydrocarbons. Experiments were conducted in the dual 90m3 environment chamber at UCR/CECERT and modelling of gas-phase chemical reactions were guided by the SAPRC model gas-phase chemical mechanism along with measurements of gas species including ozone, NOx, VOCs, aerosol number and volume time traces as well as aerosol density, volatility and bulk chemical composition. For the same total NOx injected, the timing of the NOx injections significantly influenced the SOA formation in the system by altering the gas-phase chemical reactivity of the system that the VOC precursor reacted in. Changes in SOA formation along with chemical and physical characteristics of the resulting aerosol will be discussed.

7AC.35

Volatility and Chemical Characterization of Secondary Organic Aerosols Formed from Aqueous-Phase Oxidation.

SARAH SUDA PETTERS, Barbara Turpin, *University of North Carolina at Chapel Hill*

Oxidized organic matter makes up a large fraction of the global aerosol burden and exerts an important influence on regional climate, human health and wellbeing, and the visibility of distant landmarks. Secondary organic aerosol (SOA) is formed when organic gases are oxidized and their reaction products condense. Condensed organic matter formed from the aqueous oxidation of water-soluble organic gases in cloud droplets and wet aerosols is increasingly recognized to be an important SOA contributor. However, quantifying the contribution of aqueous-phase mechanisms to SOA remains challenging. A major variable in determining aerosol yield is the volatility of the reaction products of aqueous-phase oxidation. A more detailed understanding of reaction products and their volatility is needed. Here we present the experimentally-determined volatility of SOA produced by aqueous oxidation of several precursors including pyruvic acid and methyl vinyl ketone. Oxidized organic matter was produced in a batch reactor containing an aqueous mixture of dissolved precursor and hydrogen peroxide. OH radicals were produced by photolysis of the hydrogen peroxide through ultraviolet irradiation. Samples were collected at intervals and chemical characterization was performed using ion chromatography (IC) and quadrupole time-of-flight mass spectrometry (QTOF-MS). Volatility was determined by pumping the sample through a vibrating orifice aerosol generator (VOAG), which produces a stream of monodisperse droplets of known size. Water and volatile compounds were evaporated at 20 degrees C and the particle residual volume was determined by an optical size spectrometer. The volume fraction remaining was determined by comparison of droplet residuals to the total organic carbon (TOC) in each sample, and volatility was estimated by comparison to calibration experiments using compounds of known volatility. Results show the dependence of volatility of aqueous oxidation products on concentration and on perturbations in solution pH made by the added presence of ammonium. Of particular interest are the volatilities of pyruvic acid aerosols in the context of the mechanisms of both pyruvic acid formation in the atmosphere and of aqueous aerosol formation from pyruvic acid. Recommendations for further investigation are discussed.

Comparing Organic Speciation of Biomass Burning Aerosol Produced in Laboratory Burns and Prescribed Fires in the Field. AUDREY DANG, Skyler Simon, Claire Fortenberry, Michael Walker, Christopher Oxford, Benjamin Sumlin, Jiayu Li, Jonathan Myers, Brent Williams, *Washington University in St. Louis*

Both laboratory and field measurements of chemical source profiles contribute to our understanding of organic aerosol, which negatively affects human health and impacts global radiative forcing. While laboratory experiments allow more careful control of sources, field measurements capture realistic emission conditions. For example, the chemical composition of biomass burning organic aerosol depends on combustion phase (e.g., flaming or smoldering) as well as the fuel type (e.g., oak or lodgepole pine, leaf or heartwood), making supporting laboratory experiments necessary to differentiate contributing source types and combustion conditions in complex field observations (Fortenberry et al. 2017).

We compare organic speciation of biomass burning organic aerosol sampled during prescribed fires of forest plots at Tyson Research Center (30 km southwest of St. Louis, MO, USA) and produced during laboratory burns of biomass collected from the same plots. Both laboratory and field samples are collected on quartz filters for analysis with a Filter Thermal Desorption Aerosol Gas Chromatograph (Filter TAG). Field samples were collected below the canopy as well as above the canopy with an unmanned aerial vehicle. Individual molecular markers and positive matrix factorization (PMF) solutions of binned chromatograms are compared (Zhang et al. 2014).

7AC.37

Characterizing the Thermal Desorption Behavior of Hemiacetal and Acetal Oligomers. MEGAN CLAFLIN, Paul Ziemann, *University of Colorado*

The presence of oligomers in atmospheric aerosols has been observed both from field measurements and for particles formed in laboratory experiments. The formation of these compounds has been attributed to particle-phase accretion reactions that occur on timescales that range from seconds to a few hours. Common types of oligomers that are formed in aerosols include hemiacetals, acetals, and peroxyhemiacetals. While the existence of these compounds in aerosols has been verified, their detection using preferred methods by the atmospheric community, such as online mass spectrometers that utilize thermal desorption, can be difficult due to decomposition or fragmentation. Thermal desorption methods, like the FIGAERO-CIMS, offer the opportunity to detect compounds separated by their volatility. Yet how oligomers, especially those that form via reversible reactions, respond to thermal desorption is unclear. There has been evidence that under some conditions, the thermal ramping can cause the oligomers to revert to their monomer building blocks, and thus when detected they would not reflect the true aerosol composition.

To study the effects of thermal desorption on hemiacetals and acetals, both synthesized standards and the SOA formed from the reaction of β-pinene with NO_3 radicals were investigated. Previously, we have shown that >90% of the β-pinene SOA is made up of hemiacetal and acetal oligomers. Therefore, this system provides an opportunity to look at the thermal desorption properties of real SOA that has been carefully characterized and is made almost entirely of oligomers.

The thermal desorption behavior was studied using two types of mass spectrometers. The first was a Temperature Programmed Thermal Desorption Particle Beam Mass Spectrometer (TPTD-PBMS) which uses electron ionization and a thermal desorption ramp rate of 2 ^{0}C min^{-1}. This instrument was used to study how these classes of compounds are ionized in real time, by instantaneous vaporization, versus how they behave when slowly desorbed by heating. The second was a Chemical Ionization Ion Trap Mass Spectrometer (CI-ITMS) equipped with a Direct Insertion Probe (DIP) that uses a thermal desorption ramp of 10 ^{0}C min^{-1}, a ramp rate that is comparable to that used with the FIGAERO-CIMS.

The results of our experiments show that when hemiacetals are analyzed in real time they are ionized as the intact oligomer. However, when they are slowly heated using a thermal desorption method the hemiacetals decompose and are instead ionized as their monomers. This effect was not seen for acetals, which were ionized as the intact oligomer for both real time and thermal desorption analyses.

Our intention of characterizing how these types of oligomers respond to thermal desorption detection methods is to give insight on the interpretation of data for aerosol systems that are likely to contain these classes of compounds. Without accounting for decomposition of oligomers, the consequence is likely misassigning the volatility of an aerosol and thus misrepresenting the physical properties of the particle.

7AC.38

Gas-particle Partitioning and Temperature: Competition Between Vapor Pressure Dependence and Phase-state. CHEN LE, Weihan Peng, Mary Kacarab, David R. Cocker III, *University of California, Riverside*

Secondary Organic Aerosol(SOA) formation potentials from Volatile Organic Compounds(VOC) precursors are often described assuming that partitioning species are at thermodynamic equilibrium as is the case in the classic two-product SOA partitioning model and in the volatility basis-set model. Temperature dependence on SOA formation following these models can then be estimated using the Clausius-Clapeyron vapor-pressure temperature dependence relationship and an assumed enthalpy for the condensable species. Describing gas-particle partitioning using this model assumes: 1) temperature change in the system does not alter the composition in the system; 2) that equilibrium within the system is rapidly achieved. Therefore, it should be expected that the temperature of the system will determine gas-particle partitioning equilibrium regardless of the temperature that oxidation occurred at.

Observations in the CE-CERT environmental chamber over the past decade demonstrate: 1) far more aerosol is formed in systems operated at 5ºC and then warmed to 25ºC than in systems operated at 40ºC and cooled to 25ºC, even after accounting for chamber wall effects; 2) gas-particle partitioning cycling between temperatures for a single experiment regardless of initial temperature, however, is reversible and can be described applying an either empirical or semi-empirical enthalpy of vaporization.

This study discusses these apparent observational anomalies. The effect of aerosol-phase state and viscosity is evaluated using the dual-differential mobility analyzer technique described by Rothfuss and Petters (2016) in the dual-Teflon indoor chamber at CE-CERT. The technique induces coagulation between two oppositely charged particles and relates viscosity to the relaxation time for the dimer to return to a spherical shape. The effect of phase-state along with chemical kinetics at the different experimental temperatures are used to explain the apparent non-equilibrium temperature effects observed. Strong relaxation time temperature dependencies were observed during environmental chamber temperature shifts that suggested that mass-transfer related kinetic effects were responsible for the irreversibility observed between gas-particle partitioning of SOA formed at 5ºC and 40ºC. This work focuses on observations of temperature effects from the α-pinene dark ozonolysis and m-xylene – NOx photooxidation system including gas-particle partitioning and changes to chemical composition.

7AC.39

Exploration of Potentially Increasing SO2 Oxidation in the Eastern United States. BRET SCHICHTEL, Anthony Prenni, Jenny Hand, Scott Copeland, Kristi Gebhart, John Vimont, William Malm, Jeffrey Collett, *National Park Service*

In the early 1990s, ammoniated sulfate accounted for about two-thirds of the fine particulate mass in the rural eastern U.S. as measured by the Interagency Monitoring of Protected Visual Environments (IMPROVE) program. Particulate sulfate also had a distinct seasonal cycle, with summer concentrations a factor of 2 larger than in winter. In the ensuing 25 years, sulfur dioxide (SO2) emissions have decreased by about a factor of 10, resulting in well-documented decreases in SO2 measured by the Clean Air Status and Trends Network (CASTNET) program and particulate sulfate measured by the IMPROVE and CASTNET programs. The reductions in particulate sulfate were commensurate with the SO2 emission reductions until about 2008, when the trends diverged, after which time smaller decreases in particulate sulfate occurred for every unit decrease in SO2 emissions. The ratios of ambient sulfate to SO2 also increased in CASTNET measurements. In addition, particulate sulfate seasonality was substantially reduced throughout the eastern U.S. One explanation for this recent nonlinear response of particulate sulfate to changes in SO2 emissions is that the SO2 to sulfate oxidation may have become more efficient, resulting in a greater fraction of SO2 being converted to sulfate. Alternatively, these observations may be driven by increased background sulfate concentrations from international sources or primary emissions of particulate sulfate. In this presentation we will explore these possible causes and present the available evidence suggesting that the fraction of SO2 oxidized to sulfate in the eastern U.S. has increased over the past 10 years.

7AC.41

Trends in Organic Aerosol Mass and Functional Group Composition in the SouthEastern Aerosol Research and Characterization (SEARCH) Network from 2008 to 2016. ANN DILLNER, Alexandra Boris, Andrew Weakley, Bruno Debus, Eric Edgerton, Stephanie L. Shaw, Satoshi Takahama, *University of California, Davis*

Organic aerosol (OA) concentrations are on the decline in the Southeastern US. This presentation covers trends in OA and its composition as described by organic functional groups at five sites in the Southeastern Aerosol Research and Characterization (SEARCH) Network over a recent 9-year period. Functional groups are estimated in particulate matter (PM) filter samples using a Fourier transform infrared spectroscopy (FT-IR) technique. The vast filter archive of SEARCH samples, stored cold since 2008, enables the application of FT-IR to nearly a decade of aerosol samples at two urban-rural paired sites and a coastal site. OA contains thousands of molecules, but typically only ~5-30% of OA mass is identified in atmospheric PM composition studies. However, in this work FT-IR functional group measurements enable the quantification of nearly all OA sample mass. In addition to describing trends in OA composition, we will estimate the ratio of organic matter to organic carbon concentration (OM/OC) in each analyzed sample to provide a metric for aerosol oxidation and to provide a tool for converting routinely measured OC concentrations to OM.

The contribution of carbonyl, carboxylic acid OH, aliphatic CH, and alcohol OH to OA mass are measured at two urban/rural pairs (i.e. Atlanta and Yorkville, GA; Birmingham and Centreville, AL) and a coastal site in Florida from 2008 to 2016. To measure functional groups, laboratory standards are made by aerosolizing compounds containing each functional group and collecting them on PTFE filters using a SEARCH sampler. The laboratory standards are analyzed by FT-IR, and the resulting infrared spectra are used to develop partial least squares calibration models. The calibration models used in this study expand upon previous work to include a broader, more atmospherically relevant selection of chemicals. This includes chemicals representing oxidation products such as multifunctional carboxylic acids and a tetrol, carboxylate salts demonstrating interaction between inorganic and organic species, levoglucosan to represent biomass burning emissions, and an amino acid to represent the contribution of reduced organic nitrogen species. This work better quantifies carbonyls in particular, as compared to prior work. This work also demonstrates the spatial and seasonal variability and trends in functional groups and OM/OC within the diverse and abundant OA collected in the SEARCH network.

7AE.1

Investigation of Ground Level Aerosol (PM2.5) with Different Mode of Transports in Dhaka, Bangladesh. AHMAD MAJUMDER, M.D. Hossain, Abdullah Nayeem, *Stamford University Bangladesh*

Air pollution is considered as a threat to the environment of the modern cities. The study was carried out through the field experiments, collection and analysis of data from both primary and secondary sources to determine the concentration of particulate matter and causes of pollution.The study reviewed the suspended solid particulates specifically $PM^{2.5}$ and compared between different categories roads which are Non-motorized, Mixed and Motorized and also with Environment Quality Standards (EQS) for Bangladesh published by the Department of Environment (DoE).This study outlinesalso make a co-relation between concentration of the particulate matters and increasing of motorization.$PM^{2.5}$ was measured and conducted traffic volume survey in 12 sites across the city in Dhaka (August 2017). Levels in mixed and motorized areas were on average 182 and 272% higher, respectively, than non-motorized. Surprisingly, short term measurements (~8hrs) in predominantly mixed and motorized areas already exceeded the maximum recommended limit for 24hrs (65 $\mu g/m^3$). This suggests a much higher pollution potential over a typical 24hrs period in motorized traffic areas. The study hypothesized that uncontrolled motorization is major cause of air pollution especially $PM^{2.5}$ in the Dhaka city and the impact of these particulate matters on public health and environment are beyond the tolerable limits.The study has come up with some recommendations regarding improvement of air quality in respect of particulate matter and emphasized for further comprehensive study on other parameters of air pollution around Dhaka city.The study drew conclusion that the overall air quality regarding the particulate matter already exceeded highest standard limits of Bangladesh. The study recommended several measures to mitigate and prevent the harmful impacts and to improve the air quality of Dhaka city.

Key Words: Pollutant, Air pollution, Motorized, Non-motorized, Human health.

7AE.2

Health and Economic Effects of Wildfire in US. KAIYU CHEN, Hao Guo, Hongliang Zhang, *Louisiana State University*

Nowadays wildfire is the largest source of air pollutants that greatly changes landscape with impacts on human health, large scale climate changes, social economy and ecosystem in the U.S. The Community Multi-scale Air Quality (CMAQ) model is applied to simulate potential impacts on air pollutants due to wildfire in 2011. The National Emissions Inventory (NEI) 2011 is used to generate anthropogenic emissions with the Sparse Matrix Operator Kernel Emissions (SMOKE) emission processing model. The wildfire emissions are generated based on the fire inventory from National Center for Atmospheric Research (NCAR). Contributions of wildfires to air pollutants concentrations are quantified and the estimate health and economic outcomes are estimated using the US EPA developed Environmental Benefits Mapping and Analysis Program (BenMAP). Premature mortality, non-fatal heart attacks, aggravated asthma and economic risk are estimated to represent impact of wildfire and help to improve air quality controlling strategy.

7AE.3

Quantifying the Impact of Wildfires on Air Quality and Human Health: the Case of Equatorial Asia. PAOLA CRIPPA, Stefano Castruccio, Mohd Talib Latif, M.S.M. Nadzir, D. Dominick, Mikinori Kuwata, Abhinav Thota, M.I. Mead, Christine Wiedinmyer, *University of Notre Dame*

Forest and peat fires have become a frequent occurrence in Equatorial Asia as a result of a warmer and drier climate, uncontrolled agricultural practices and intentional ignition. Air pollutants from wildfires, including carbon monoxide (CO) and particulate matter (PM), can be transported in the atmosphere for thousands of kilometers from the originating fires and thus significantly impact air quality and human health over wide areas. In this work we focus on the extreme fires occurred in Fall 2015 in Equatorial Asia and assess air quality conditions and associated population exposure. Quantifying the impact of wildfires on human health is currently limited by the lack of integrated studies including both direct Earth observations, modeling tools and health records. In our study we apply a state-of-the-art regional model (WRF-Chem) at high spatio-temporal resolution to characterize air pollution episodes from the 2015 wildfires in Equatorial Asia. Simulated PM and CO concentrations are evaluated against satellite observations and data from a dense ground-based network and indicate high skills of WRF-Chem in capturing both the spatio-temporal variability and magnitude of these events. We estimate that, during September and October 2015, 69 million people were persistently exposed to unhealthy air quality conditions. Further, the short term exposure to the enhanced PM2.5 concentrations from wildfires may have caused 11,880 (6,153–17,270) excess mortalities. Our results indicate that by using a high resolution regional model we can provide unique information to policy makers to coordinate the effort between emitting and exposed countries in improving air quality and reducing population exposure.

7AE.4

Spatially-Resolved Comparison of Traffic and Cooking-Related PM1 Emission in Urban Area and Their Threat to Public Health. Peishi Gu, Zhongju Li, Qing Ye, Ellis Shipley Robinson, Joshua Apte, Allen Robinson, ALBERT PRESTO, *Carnegie Mellon University*

Spatial gradients of PM1 concentration (particulate matter under 1 mm in diameter) have been discovered near local sources, such as highways and restaurants, etc. The population that lives or works in these impacted regions is often exposed to higher than background PM concentration, and this may increase their short-term and long-term health risks. From a perspective of regulation, it is essential to understand what sources are responsible for the elevated concentration, and how are population impacted by the sources spatially. In this study, we have utilized a mobile sampling platform coupled with HR-ToF-AMS and Aethalometer to investigate the spatial distribution of PM1 in Pittsburgh, which is a major city in the northeastern United States. We performed extensive mobile measurement in areas of various types of land-use. Cooking and traffic-related organic aerosol (OA) were resolved as the major primary sources by positive matrix factorization (PMF). We included the spatially resolved statistics of traffic volume, restaurant counts and population, and performed GIS analysis based on a 200-meter grid overlay on the sampling domain. We have found that more than 80% of the population is located within the 200-meter range of identified local sources, and the existence of such sources are strongly associated with the elevated PM1 concentration. For OAs, cooking is more important compared to traffic as a primary source, based on both the concentration and the impacted population. However, since diesel engines dominate the emission of black carbon in urban areas, traffic source still poses a greater threat to public health than cooking.

7AE.5

Efficiency of Anti-Pollution Masks in Three Microenvironments. BORIS GALVIS, Camila Figueredo, Fabian Moreno, Jorge Pachon, *Universidad de La Salle*

We tested different commercially available masks to determine the reduction in exposure and dose of fine particulate and black carbon that each might provide. We evaluated them inside the Bogota's BRT buses, on a pedestrian route in the city's downtown area and on a bike path using two sets of DustTrack DRX (TSI, Shoreview, MN) and AE51 microaethalometer (AethLabs, San Francisco, CA). One set sampled air directly from the microenvironments whereas the other did it through the masks. We used a mannequin head as an adapter for the masks to the inlets of the instruments and to take in to account how the masks fit. Both sets operated simultaneously and concentrations measured were used to estimate a possible reduction in exposure and potential inhaled dose of aerosols. Results might be used to show citizens how to reduce their exposure during commutes in a megacity and to point towards the most effective way to prevent effects during an air pollution episode.

7AE.6

Air Quality with Particulate Matter Assessment in Road Tunnels in China and Pakistan. ZONA ZAIDI, Zulfiqar Ali, Romaisa Qureshi, Irfan Zainab, Syed Turab Raza, Zaheer Ahmad Nasir, Ian Colbeck, Liu Weilong, *University of the Punjab, Lahore, 54590, Pakistan*

Breathing in road tunnels may endanger your health. Poor air quality on roads and in tunnels threatens the health and well-being of people travelling in vehicles. Air pollutant in road tunnels could be in the form of a solid particle, liquid droplets or as gases. The objective of this research was to assess air pollution in 44 road tunnels of China i.e., Chengdu to Lang Musi Zhen (32°39'35N, 103°36'09E at 2876m elevation) and 5 tunnels of Pakistan i.e., Shishkat to Attabad (36◦39.747N, 074◦50.586E at 2839m elevation). Metrological parameters, CO_2 concentration along with different particulate matter were assessed using standard protocol. Independent t-test showed PM_1, $PM_{2.5}$, PM_{10} and PM_{total} concentrations for China and Pakistan were non-significantly different from each other with p-value 0.071, 0.069, 0.071 and 0.07 respectively while temperature, humidity and carbon dioxide were significantly different from each other having p-value 0.000, 0.000 and 0.011 respectively which are also justified by Pearson co-relation. Spearmen's correlation assessed relationship between different parameters and their associative behaviour and showed temperature was non-significantly correlated with particulate matter, humidity and CO_2. While $PM_{2.5}$, humidity and CO_2 were significantly correlated. CO_2 concentration as linear with vehicular emission was higher inside of tunnel in china but traffic blockage in Pakistan rise its high levels outside of it. The confinement of tunnel's air aided by its boundary along with massive traffic becomes the major factor in rise of temperature inside of tunnel along with humidity as water drops trap inside of it due to lesser air currents.

7AE.8

Emission of Particulate Matter, VOCs and PAHs from Different Asphalt Mixes. MENG XIU, Xianyu Wang, Jochen Mueller, Andrew Beecroft, Lidia Morawska, Phong Thai, *Queensland University of Technology*

Asphalt is widely used for road pavements across Australia, and is considered heavily resource intensive. On the other hand, in Australia, millions of tyres reach the end of their service life every year and need to be disposed of. New technology allows end-of-life tyres to be processed as crumb rubber and recycled in road construction as an additive to save materials and reduce waste, with the product known as crumb rubber modified (CRM) binder. However, application of asphalt mixes, including the CRM binder, can generate toxic fumes and emissions including those of total suspended particles (TSP), volatile organic compounds (VOCs) and polycyclic aromatic hydrocarbons (PAHs). These pollutants not only deteriorate air quality in the immediate vicinity, but also raise health risks to paving workers. Research outcomes regarding environmental and health issues associated with the application of CRM mix are still scarce.

This study, therefore, aims to compare the levels of air pollutants during pavement of different asphalt mixes including the CRM mix, as well as assess the risk for their emissions. Two field investigations were performed on several different construction site. Emission factors of TSP, VOCs and PAHs from different asphalt mixes were measured using portable flux chambers, connected simultaneously with a vacuum canister (for VOCs sampling) and two active air samplers (for TSP and PAHs sampling respectively). A total of 60 VOC analytes and 13 PAH compounds are analysed by a gas chromatography-mass spectrometer (GC-MS) and a gas chromatograph coupled to a high-resolution mass spectrometer (GC-HRMS), respectively. For personal exposure, a Dustmate device is provided to the workers (a paver driver and a screed operator) to monitor personal exposure to particulate matter (PM), including $PM_{2.5}$, PM_{10} and TSP, which may be inhaled via the respiratory pathway.

In the results of the field study 1, TSP levels were found to be 2.5 times higher for the CRM operation than PMB, and higher than the Queensland air quality objective. Apart from the appearance of some alkanes and naphthalene during the construction work, the levels of other VOCs are mostly below limit of report. Although there was an increase in the level of BaP and PAHs in the ambient air during and shortly after the construction, the highest concentrations measured (0 – 3 hrs after spray) in both treatments were much lower than the Queensland air quality objective. The results of the field study 2 showed that CRM hot mix was likely to produce higher concentration of air pollutants (VOCs and PAHs) than both CRM warm mix and polymer mix, even though no significant difference ($p>0.05$) was observed for levels of TSP, PM_{10} and $PM_{2.5}$ at work site. The data from this study is expected to contribute to the overall assessment of the comparative risk of using ground tyre rubber techniques in road paving industries in Queensland.

7AE.9

Assessment of Exposure to Bioaerosols and Heavy Metals in a Material Recovery Facility in Central Taiwan. HUI-MING LIU, *Hungkuang University*

Recently the world's energy and raw materials availability is progressively dwindling result in rapid development of the materials recycling industry. Bioaerosols and metal dusts are accompanied during materials recycling process and harm to human health. Hence, it is necessary to investigate the exposure to metals and bioaerosol among workers at resource material factories.

This study is to assess exposure of bioaerosols and metals from different working areas at a material recovery facility (MRF) in central Taiwan. In order to investigate species, concentrations and size distribution, airborne fungi and bacterial were taken by using an Anderson 6 stage viable impactor and Microbial Air Monitoring System-100 (MAS-100). Airborne dusts were sampled by a ten-stage micro-orifice uniform deposit cascade impactor (MOUDITM), followed analyzed concentrations of Cu, Zn, Cd, Cr, Mn, Ni, Pb and W by inductively coupled plasma optical emission spectrometry (ICP -OES).

In this study, the bioaerosol concentrations did not exceed the standard of occupational exposure limit. Aspergillus was the most predominant fungal isolates, with a mean concentration of 965.3 CFU/m3. Staphylococus warneri was the dominant bacterial isolates identified. Meanwhile, the most prevalent fungi occurred in the size range of 3.3~2.1 µm at recycling of PET bottles area. The most prevalent bacteria were found at recycling of metals area in ≧7.0 µm size range. The major metals in airborne dusts were Zn and Pb， with mean concentrations of 0.71 µg/m3 and 0.64 µg/m3, respectively.

This study indicated that relatively humility was associated with bioaerosol concentrations in MRF environment. Many major indicators of allergenic and toxigenic airborne fungi such as Aspergillus and Staphylococus warneri were found in the material recovery environments. The results obtained from this study may provide useful information for the implementation of management for material recovery facility.

7AE.10

Exposure to Fine Particulate Matter and Black Carbon during Cycling: A Comparison between London and São Paulo.

VERONIKA SASSEN BRAND, Prashant Kumar, Maria de Fatima Andrade, *University of Sao Paulo*

People, during commuting, mainly through active transport, like cycling and walking, are exposed to higher concentrations of traffic emissions due to their proximity to on-road vehicles. Several epidemiological studies relate particulate matter (PM), including the black carbon (BC) fraction, exposure to both mortality and morbidity caused by respiratory and cardiovascular diseases. As a part of ASTRID Project (Accessibility, Social justice and Transport emission Impacts of transit-oriented Development strategies) and PEDALS project (Particles and Black Carbon Exposure to London and Sao Paulo Bike-Lane Users), we did a comparative assessment of commuters exposure to both fine particles ($PM_{2.5}$) and BC in specific cycle routes in the cities of London (UK) and São Paulo (Brazil). In both cities, we measured, during the peak and off-peak hours, $PM_{2.5}$ and BC concentrations using a personal exposure monitoring backpack equipped with a MicroAeth AE51 to monitor BC, a DustTrak II Aerosol Model 8530 monitor in Brazil and a GRIMM EDM 107 aerosol spectrometer in the UK to measure $PM_{2.5}$ concentrations. Three origin-destination (O-D) routes pairs were chosen in both cities. Each O-D pair gave two routes, the first one being along busy/major roads and the second one presumed to be less polluted since we preferably passed through green/blue/quiet areas. Thus, the aim of this work was to: (1) compare the exposure to $PM_{2.5}$ and BC while cycling during peak and off-peak hours at the chosen routes, (2) identify main pollution hotspots resulting in increased exposure, (3) investigate the correlation between the measured concentrations and the type of cycle lane/presence of vegetation/proximity to water bodies, and (4) calculate the inhaled respiratory deposition doses (RDD). We observed that São Paulo had the highest mean concentration of BC (11 µg/m³) and $PM_{2.5}$ (29 µg/m³), while London, in average, showed 5 µg/m³ of BC and 17 µg/m³ of $PM_{2.5}$. $PM_{2.5}$ and BC concentrations were always higher during the morning peak hours when compared to the evening peak hours, except in São Paulo, where the evening peak was the one with the highest mean concentration of BC (11.4 µg/m³). There was also found that cyclists using a route, which passed through the green/open areas and had relatively less traffic volumes, found to be less exposed to both pollutants assessed. The findings in this work are important to policy makers and urban planners when planning new cycle networks with less exposure levels, not only in the two urban areas assessed, but also as a model to other urban locations.

7AM.1

Atmospheric Relevance of Laboratory Experiments on Ion Composition Based on Ion Composition Simulation. KALJU TAMME, Aare Luts, Urmas Hõrrak, Jaan Salm, Heikki Junninen, *University of Tartu*

Composition of small atmospheric ions depends on trace gas composition and concentrations. Atmospheric ions are produced by ionization sources and evolve through a cascade of collisions between ions themselves and neutral trace gas molecules, and are absorbed by recombination, coagulation with particles and diffusion onto walls. Ionization is initialized by collisions of high energy particles from outer space or by radioactive decay.
The main motivation for conducting simulations was to evaluate the effects of temperature, sulfuric acid concentration and absence or presence of CO_2 in reaction on the chemical composition of ions. This study was aimed to give an insight into atmospheric applicability of laboratory experiments that are often conducted in N_2 or synthetic air environment. Among others, those experiments conducted in CERN the Cosmics Leaving Outdoor Droplets (CLOUD) were absent of CO_2. Results from CLOUD showed higher ion concentration and ion-induced nucleation than measured in Hyytiälä, SMEAR station, Finland (Wagner et al, 2015).

The ion-kinetic model introduced by authors was used. Model contained 522 ion-molecule reactions with 166 ion species and 127 neutral compounds. Both, the time variations of the concentrations and the steady state concentrations of individual ion species were calculated. Technically, the time variations were simulated as the time evolutions of individual ion species by way of ion-molecular reactions that started from the primary ions (in this study, 5% O^- and 95% O_2^-). The neutral species were regarded as constants. This assumption was justified because (atmospheric) concentrations of these neutrals were many orders of magnitudes higher than those of ions. The steady state concentrations were computed by the model considering both, the time evolution of the individual ion species and the parameters, that determine the ionization and sink characteristics in a given environment. A more detailed description of the model and some examples where it was used can be found in (Luts and Parts, 2002; Parts and Luts, 2004; Luts and Salm, 1994; Luts, 1994).

We used our model to simulate experiments with absence and presence of CO_2, with different temperatures and different concentrations of H_2SO_4. When compared simulations where the changing parameter was CO_2, we found that in the presence of CO_2 the NO_3^-concentration were still higher than in those made without CO_2. Also in the simulations where CO_2 was present the O_3^- had much lower concentration. As a conclusion we found that CO_2 has an effect on steady-state concentrations of ions. On simulations where the changing parameter was H_2SO_4, we saw that when H_2SO_4 concentration was higher the NO_3^- concentrations were lower. Investigating the behavior of cluster ion composition from temperature, we found that on most simulations NO_2^- and NO_3^- had higher concentrations at higher temperature.

This work was supported by European Regional Development Fund, project MOBTT42 under Mobilitas Pluss programme, and by the Estonian Research Council Projects IUT20-11.

Comparison of Different Aerosol Dynamics Models Based on Accuracy and Computational Time. GIRISH SHARMA, Sukrant Dhawan, Zhichao Li, David I. A. Dhanraj, Pratim Biswas, *Washington University in St Louis*

Numerical simulation for aerosol dynamics is indispensable tool for predicting the evolution of particulate systems, which is useful for in-depth understanding of the experimental measurements, in atmosphere as well as aerosol reactors. These models permit the interaction of complex physical processes through simulation, which are then related to the experimental data. Different aerosol dynamics phenomena like chemical reaction, nucleation, condensation, coagulation, sintering, aggregate formation, and charging are described using general dynamic equation.

Different numerical schemes have been developed over the years to simulate these processes which include method of moments, discrete model, sectional model, discrete-sectional model, and modal model. Each of these schemes has its own advantages and disadvantages. Among these, discrete representation of particle sizes is the most accurate representation of aerosol dynamics as it mimics the aerosol dynamics most closely, but this comes at a high computational cost whereas sectional model is computationally less intensive but has inaccuracies in small sizes. Method of moments and modal model are very fast but are not as accurate as sectional and discrete models. Although separate literature on all these models exists, the comparison between all the models based on their application under different conditions has not been investigated.

In this work, the aim is to investigate the performance of different aerosol dynamics models under different applications. First, different models will be compared based on the accuracy of their results. Then, these models will be compared based on the computational time required to run a simulation with the same configuration. Finally, the performance of these models will also be analyzed on different computer processors. With the better understanding of the trade-off between accuracy and computational time, a recommendation will be made on choosing aerosol dynamics model for different applications.

7AM.3

Modeling On-road Fine and Ultrafine Particle Concentrations in Los Angeles. Nu Yu, Shi Shu, Lu Zhang, Yan Lin, Jun Wu, YIFANG ZHU, *UCLA*

Air pollution is among the top threats to public health in Los Angeles. Traffic related particulate matter (PM) exposure has been linked to different adverse health effects. In this study, fine PM ($PM_{2.5}$) and ultrafine particle (UFP) concentrations were measured on roadways outside moving taxi vehicles in the Greater Los Angeles area from April to November, 2013. The total distance driven is approximately 11,000 kilometers and the total hours of field measurement is approximately 500 hours. We developed and compared four types of models to estimate UFP and $PM_{2.5}$ concentrations on freeways, arterial roads, and local surface streets: multiple linear regression models without and with temporal variance structures (MLR and sMLR models), and generalized additive models without and with temporal variance structures (GAMs and sGAMs). A backward selection procedure was used to select predictive variables from meteorological condition panel, traffic condition panel, and spatial feature panel. The modeling results show that GAMs explained the highest percentages of the total UFP and $PM_{2.5}$ variance. The MLR models generated the best cross validation (CV) results with least discrepancy from the general R^2s. The models performed the best on the data collected on arterial roads comparing with the data collected on freeways and local streets. The arterial road models generated general R^2s equivalent or above 0.40 and CV R^2s ranging from 0.34 to 0.73. All arterial road models and the local street $PM_{2.5}$ sMLR model and GAM generated both general and CV R^2s greater than 0.30. Temperature, relative humidity, vehicle speed, annual average daily traffic (AADT) and time of day variables were consistently selected by these models. These predictors, except for time of day, show positive associations with UFP or $PM_{2.5}$ concentrations, which are consistent with previous studies, and the physical and chemical properties of the traffic related UFP and $PM_{2.5}$.

7AM.4

Overprediction of Fine Aerosol Nitrate by Chemical Transport Models: The Role of Nighttime Chemistry and Mixing.

Maria Zakoura, SPYROS PANDIS, *University of Patras*

Fine particulate nitrate is often over-predicted by chemical transport models (CTMs) in areas of the Eastern US and Europe. This overprediction is especially severe during a few nights during the summer or other photochemically active periods, when CTMs predict unreasonably high nitric acid production rates. We test the hypothesis that the main reason of this nighttime aerosol nitrate overprediction is the coarse grid resolution used that cannot capture the local phenomena that take place in the plume of major sources. The CTM PMCAMx is used to simulate a summer period over the Eastern US taking advantage of the dense fine nitrate measurement networks (STN and IMPROVE) in that area.

The base case simulation with coarse resolution (36x36 km) often predicted high nighttime nitrate production rates, thus leading to widespread overprediction of aerosol nitrate levels both during the night but also during the next day. We show that this overprediction is due to the artificial mixing by the model of NO_x-rich plumes from major point and area sources with the background atmosphere. The bias for $PM_{2.5}$ nitrate decreased by 65% when the grid resolution was increased to 4x4 km. However, this improvement comes with a significant increase in the computational cost of the simulation.

The ability of a Plume-in-Grid (PiG) approach to increase the accuracy of the model with a small increase in computational cost was also investigated. The PiG sub-model was applied for the gas-phase chemistry only for the major NO_x point sources in the Eastern US during the same period. Different CTM grid resolutions were used. The results suggest that the PiG approach can be a computationally efficient method to reduce the nitrate bias in CTMs.

Despite all the above improvements, systematic discrepancies remain between the model predictions and observations. Other potential improvements in both the simulation of nitric acid partitioning, nighttime chemistry, nitric acid removal, and the emissions of ammonia are discussed.

7AM.6

Regional Climate and Air Quality Impacts of Particulate Emissions from Gasoline Direct-Injection (GDI) Vehicles.

SOROUSH ESMAEILI NEYESTANI, Rawad Saleh, *University of Georgia*

Due to their enhanced fuel economy, the market share of Gasoline Direct-Injection (GDI) engines light-duty vehicles has increased noticeably over the past decade. However, compared to the traditional port-fuel injection (PFI) engines, GDI engines have been shown to emit higher levels of particulate matter, especially black carbon (BC). BC is an efficient absorber of solar radiation, and is a prominent global-warming agent second only to carbon dioxide. This competing effect of reducing carbon dioxide emissions but increasing BC emissions raises a question regarding the net climate impacts of GDI vehicles. Back-of-envelope calculations based on the global-warming potential (GWP) of BC have shown that, on a global scale, switching to GDI vehicles has a net climate benefit of 0.5% – 2.4%[1,2]. However, due to their short lifetime, aerosol climate impacts are more important on the regional scale; therefore, the regional climate impacts of GDI vehicles might diverge from the global impacts in areas where traffic emissions are prominent.

Here, we estimate the regional (over the United States) air quality and climate impacts of switching the U.S. fleet from PFI to GDI vehicles. We use the Weather Research and Forecasting model coupled with chemistry (WRF-Chem), which simulates both chemical transport and radiative transfer. The simulations are performed at a 12 km resolution and for a period of four months (February, May, August, and November) in each season of 2011 to take into account the seasonal variability. Rapid Radiation Transfer Model for GCM (RRTMG) and Modal Aerosol Dynamic for Europe coupled with Secondary Organic Model (MADE-SORGAM) schemes are used in the model for SW/LW atmospheric radiation and aerosol mechanism, respectively. Aerosol Optical Depth (AOD) retrieved from NASA's Aerosol Robotic Network (AERONET) and Moderate Resolution Imaging Spectroradiometer (MODIS) are used to validate model calculations. Using the EPA's National Emission Inventory for 2011 (NEI-2011) as a base case, we modify the vehicle emission profiles using GDI emission data from measurements[1]. By comparing the base case with the modified one, we obtain spatially and seasonally resolved changes in carbonaceous aerosol concentrations and the consequent radiative effect.

Diffusion Limitations and Shielding Effects in the Ozonolysis of Polycyclic Aromatic Hydrocarbons Embedded in Secondary Organic Aerosols. BRIAN HWANG, Shouming Zhou, Pascale Lakey, Jonathan Abbatt, Manabu Shiraiwa, *University of California, Irvine*

Benzo[a]pyrene (BaP), a key polycyclic aromatic hydrocarbon (PAH), is known as a carcinogen and mutagen. BaP is often associated with soot particles emitted from biomass burning and incomplete combustion. In the atmosphere, BaP can react with oxidants such as ozone forming more toxic compounds including quinones and epoxides. Thus, it is important to quantify the kinetics of the heterogenous reaction between BaP and ozone, which is investigated in this study. The decay kinetics of BaP by ozone were measured by applying direct analysis in real time mass spectrometry (DART-MS) [1]. BaP was embedded in bis(2-ethylhexyl) sebacate or alpha-pinene secondary organic aerosol material. To investigate the impact of phase state on reaction kinetics, experiments were conducted at different relative humidities of < 5%, 50%, and 85%.

We applied the kinetic multi-layer model of aerosol surface and bulk chemistry, (KM-SUB) [2] to model the experiment data. KM-SUB explicitly treats mass transport and chemical reaction at the surface and in the bulk. To obtain the distribution of kinetic parameter values to fit the experiment data with modeling, we applied the Monte-Carlo genetic algorithm method [3]. In this method, kinetic parameters are randomly chosen to fit the experimental data and these values are optimized by genetic algorithm. By considering the decomposition of ozone and subsequent formation of reactive oxygen intermediates [4], the concentration dependence of BaP decay was reproduced using a single set of kinetic parameters. The obstruction theory was applied to account for inhibition of bulk diffusion of the BaP and ozone due to accumulation of reaction products at the surface and in the near-surface bulk [5]. With this approach, we were able to capture the initial fast kinetics followed by slow decay of BaP. We also analyzed how mass transport, rate of surface or bulk reaction, and diffusion of BaP and ozone may limit the overall reaction kinetics, finding that the reactions were controlled by bulk diffusion of BaP from the bulk to the surface at longer reaction times.

Addition of Charge Model to Coupled Flow-Aerosol Dynamics for Glowing Wire Conditions. KUNAL GHOSH, S.N. Tripathi, Manish Joshi, Y.S. Mayya, Arshad Khan, B.K. Sapra, *IIT Kanpur*

Glowing wires generate charged nanoparticles via electrical heating which have been used earlier in association with mobility classification, but the phenomenon is complex and not fully understood. C. Peineke, A. Schmidt-Ott[1] explained generation of negative particle charge by thermoemission of electrons and positive particle charge by surface ionization of impurity atoms with low ionization energy. Such impurities are inevitably present even in high-purity metals. The role of charge, for such conditions, via coupled flow aerosol dynamical equation has not been studied. Our previous work discusses CFD coupled aerosol microphysics model (without charge) in context of aerosol generation from a glowing wire. In the present work, we have added particle charge to aerosol dynamics sub-modules (ion-induced nucleation, charged particle coagulation[2], electrostatic dispersion[2]) along with Navier Stokes equations. The model is also suitably modified to include buoyancy coupled K-Epsilon turbulence scheme. Coupled flow-aerosol dynamics equation was solved numerically and in implicit scheme. Wire composition and temperature (wire surface and cell domain) were obtained/measured, to be used as input for the model simulations. The aerosol dynamics scheme has been tested for charged aerosol particles by model studies against published results and the complete model was validated against measured temporal evolution of total number concentration and size distribution at the outlet of hot wire generator cell.

Model simulations showed significant effect of fluid properties and charge on aerosol dynamics if charge level is higher than the Boltzmann equilibrium charge limit for less than 1 µm particles. Experimental results have been compared with model simulations made for unipolar as well as bipolar charge distribution function. Although tuned specifically for the present context (i.e. aerosol generation from hot wire generator), the model can also be used for diverse applications e.g. emission of particles from hot zones (chimneys, exhaust), fires and atmospheric cloud dynamics.

Aerosol Nucleation Activated by Inducing Factors in Coal-Fired Flue Gas: A Simulation Study. CHENGSI LIANG, Chenghang Zheng, Zhengda Yang, Yi Wang, Weiguo Weng, Xiang Gao, *Zhejiang University, China*

Aerosol nucleation is an important process in the formation of aerosols in flue gas from coal-fired power plants. Ultrafine particles will form in desulfurization tower because of the huge drop in temperature, which is hard to be removed and may pollute the environment. Molecule dynamics (MD) is an approaching way to study the nucleation without the huge calculated amount to get the force between different kinds of molecules and clusters. Based on the fact that the number of water molecules is much more than other kinds of molecules in the unit volume flue gas, the model of cluster, which contains one inducing molecule in the center, like a sulfuric acid molecule or charged molecule, and multilayer water molecules around it, was established. The distribution of water molecules around the center molecule were acquired by calculating the structure of clusters with different numbers of water molecules. And the force field around the cluster was acquired by calculating the change of free energy when one more water molecule move towards to the cluster. All of the above calculations were realized through the density functional theory (DFT) method. It found that, comparing to pure water vapor nucleation, the extra effects from the center molecule to the water molecules which are in the same water molecules layer are similar, and the extra effect decreases along when the layer increases until it can be ignored. Therefore, the influence of the center molecule on finite layers of water molecules was considered to simplifying the model. This simplified cluster model was used to investigate nucleation process in dynamical method. This work figured out the nucleation rate and dew point of aerosol in different conditions, which basically correspond to the acid dew point by measurement.

7AM.11

Carbon-, Oxygen-, and Size- Resolved Model to Simulate the Microphysics, Chemistry, and Thermodynamics of Biomass Burning Organic Aerosol. ALI AKHERATI, Christopher Cappa, Jeffrey R. Pierce, Shantanu Jathar, *Colorado State University*

Globally, biomass burning – that includes wildfires, agricultural, prescribed and landfill burning – is an important source of organic aerosol (OA) to the atmosphere. Emissions of biomass burning organic aerosol (BBOA) vary substantially with the fuel type, burn conditions, and ambient conditions and atmospheric mixing and photochemical oxidation are expected to alter the size, mass, and composition of BBOA. Yet, there are large uncertainties when it comes to understanding the physicochemical evolution of BBOA and its consequent impacts on air quality, climate, and human health.

In this work, we will develop a state-of-the-science OA model that combines the two-dimensional statistical oxidation model (SOM) with the TwO-Moment Aerosol Sectional (TOMAS) model.The SOM uses a two-dimensional carbon-oxygen grid to track the gas- and particle-phase chemistry, gas/particle partitioning, and properties of gas- and particle-phase organic precursors and products. The TOMAS model uses two moments, that of number and mass, of the aerosol size distribution to model processes of nucleation, condensation, and coagulation. This updated model, resolved in dimensions of carbon number, oxygen number, and size, will simulate the microphysics, chemistry, and thermodynamics of BBOA and include the following processes: (a) semi-volatile and reactive POA, (b) SOA formation from semi-volatile, intermediate-volatility and volatile organic compounds, (c) multi-phase, multi-generational aging that includes functionalization and fragmentation reactions, (d) low-volatility SOA formation from autoxidation and oligomerization reactions, (e) influence of vapor wall losses encountered in laboratory SOA formation experiments, and (f) phase state of OA. The model will be evaluated against chamber and flow reactor experiments performed at the Fire Laboratory in Missoula, MT as part of the FLAME and FIREX campaigns to identify the most important precursors, pathways, and experimental artifacts that control the size, mass, and composition of BBOA.

Insight from this work will be used to develop models and parameterizations for BBOA in regional and global air quality and climate models.

7AM.12

Estimation of Loss Rates from Chamber Experiment Data Using a Statistical Inverse Approach. MATTHEW OZON, Aku Seppänen, Ari Leskinen, Jari Kaipio, Kari Lehtinen, *University of Eastern Finland*

Motivations

Deposition is one of the key aerosol microphysical processes, important in large scale when considering both climate and health effects and in a smaller scale, e.g. when analyzing chamber experiments. Deposition mechanisms and rates are strong functions of size: smaller particles deposit mainly by diffusion in contrast to larger ones, which deposit by settling or due to their inertia. In this study, our focus is on estimating deposition rates in experiments, e.g. in a chamber, in which multiple processes are acting simultaneously. One might for example encounter a situation in which the concentration is high enough that coagulation is significant in addition to deposition. Then it is not straightforward to extract size dependent deposition rates just by simply examining the decrease of the number distribution.

Methods

A rigorous method to estimate size dependent deposition rates in a chamber has been to perform several separate concentration decay experiments using a monodisperse aerosol. This is, however, not necessary even for a seemingly complex case with other simultaneous disturbing processes if advanced data-analysis methods are used. Here we propose an automated method where the only assumption is that the parameters vary “slowly” over time. Our approach relies on the widely used statistical, dynamical inversion method that accounts for measurement uncertainty in a rigorous way, the Kalman Filter (KF). The KF is stable, minimizes the variance of the estimates and is easy to implement. Our implementation of the KF not only filters — improve the data quality — the size distribution, but it also estimates the global loss rates. Most importantly, this method only relies on a physical evolution model — the aerosol General Dynamic Equation — a measurement model —SMPS— and rough uncertainty estimations that are combined in the KF framework.

Results

As a proof of concept of our method we analyze synthetic data generated by solving the GDE with an accurate sectional method. The data are simulated using a time invariant, arbitrary loss rate and a size spectrum ranging from an arbitrary critical cluster size of 2nm to 2µm. In this simulation, there is no vapor present, and thus the particles do not grow by condensation and there is also no nucleation. Additionally, the data are corrupted by additive and multiplicative noise in order to resemble actual measured data. The results show that the global loss rates are well estimated. Finally, the method is applied to SMPS data from a real wall loss experiment. The estimated parameters are of the same order of magnitude as those previously manually computed, and the size dependence is similar to what is expected by the theory.

7AM.13

The Effect of Fiber Polydispersity on Filtration Modeling. SEUNGKOO KANG, Da-Ren Chen, David Y. H. Pui, *University of Minnesota*

Fibrous filters are widely used to remove aerosol particles. To design a filter with desirable filter structures and properties, estimation of filtration performance of fibrous filter media is essential. A majority of studies have modeled computational filter domains with uniform-sized fibers, i.e. the domain is composed of monodisperse fibers, while real fibrous filter media are composed of polydisperse fibers. In this study, a filtration domain composed of randomly distributed polydisperse fibers is presented with its properties, such as the thickness and solidity, the same as the real filter media. In the modeling, the collection efficiencies of filters were obtained from the numerical model using particles in the size range from 3 to 500 nm, and these efficiencies were compared to the efficiencies from experimental data. In addition, the collection efficiencies from computational domains with uniform-sized fibers were also compared in order to investigate the effect of fiber polydispersity. It was found that collection efficiencies are significantly affected for the domain with monodisperse fibers depending on the fiber size and filter types, while the domain with polydisperse fibers showed an excellent estimation of efficiencies regardless of filter types. Via the validated model, we also examined the effect of fiber polydispersity on the collection efficiency for domains having the same arithmetic mean fiber diameter and properties such as solidity and thickness. Results showed that the particle collection in filter media is affected by the degrees of fiber polydispersity, especially for particles in the size range between 10 and 100 nm. For fibrous filters having bimodal size distributions, the collection efficiency was influenced by the degrees of fiber polydispersity and the size and volume fraction in each fiber mode.

Sensitivity of Sulfate In-cloud Chemistry and CCN Activation to pH Variability and Mixing State Using a Particle Resolved Model. YU YAO, Nicole Riemer, Matt Dawson, *University of Illinois at Urbana-Champaign*

Over 50 percent of the total sulfate mass at the global scale is produced by in-cloud aqueous phase chemistry that oxidize S(IV) to S(VI), and the reactions can change the particle size distribution after cloud evaporation. It is well known that different reaction pathways contribute to these oxidation processes, and that the relative importance of the pathways depends on pH. However, for current regional and global scale models it is challenging to capture the effects of non-linearity in reaction rates that may occur due to differences in droplet composition in the highly externally mixed aerosol systems often found in the real atmosphere.

In this study, we focus on the sensitivity of sulfate formation to aerosol mixing state and related variations in pH across the particle population. We simulated several urban plume scenarios that produced populations with a wide range of different aerosol mixing states using the particle-resolved model PartMC-MOSAIC. These simulated aerosol populations were then used as the input for cloud parcel simulations including aqueous chemistry where we found the sulfuric species transition mainly between sulfate, bisulfite and hydrogen sulfate under different pH and oxidation environments. The aqueous chemistry mechanism coupled in the model is based on a reduced version of CAPRAM 2.4 developed by Ervens et al. in 2003, which includes 121 aerosol species and 178 reactions. The particle-resolved approach is well-suited for this problem because it can track the evolution of compositions in each particle, including the concentration of H+. We quantified how sulfate formation changes the CCN properties of the aerosol population after cloud evaporation and how this depends on the mixing state of the cloud-forming aerosol. The results will also be used to quantify the uncertainties of CCN properties due to the assumptions of the aerosol mixing state.

7AM.15

Quantifying Errors in CCN Concentration and Aerosol Optical Properties Caused by a Non-Interactive Coarse Mode Using a Particle-Resolved Aerosol Model. JESSICA GASPARIK, Nicole Riemer, Jeffrey H. Curtis, *University of Illinois at Urbana-Champaign*

Coarse mode aerosols are generally considered to be particles of primary origins (e.g., dust, sea salt, pollen, small pieces of rubber from automobile tires) with diameters greater than ~2 µm. They are emitted into the atmosphere through mechanical processes and have a lifetime on the order of hours to days. Although this is a relatively short lifetime, many coarse mode particles still have sufficient opportunities to interact with finer mode aerosol particles (including Aitken, and accumulation modes) by coagulation, or provide surface area where secondary aerosol material can condense on, causing changes in the distribution of aerosol number mass. However, in many global models the coarse mode is treated as non-interactive, meaning they do not consider coagulation of coarse mode particles with the rest of the distribution and interaction with the gas phase. While this reduces computational cost, it may introduce significant error in predictions of the size distribution, cloud condensation nuclei (CCN) concentrations, and aerosol optical properties. The objective of this study is to assess the interactions between the coarse mode with other particle size ranges and determine the conditions where it is acceptable to treat the coarse mode as non-interactive.

For this study, we used a particle resolved model, PartMC-MOSAIC coupled with the WRF model. The model resolves the aerosol composition on a per-particle level in a Eulerian single-column domain and couples the aerosol and gas-phase chemistry with the meteorology. We constructed a suite of scenarios representative of a large urban area and simulated the evolution of aerosols of different emission types due to coagulation, condensation of secondary aerosol, and vertical mixing within the column. We varied the emissions of coarse mode and finer modes, particularly from combustion sources along with the vertical mixing by turbulent diffusion within the column. In each scenario, we compared the aerosol properties when the coarse mode is treated as interactive versus non-interactive, with respect to time and height. Based on this error, we identified conditions when it is acceptable to consider the coarse mode as non-interactive.

Soil NOx Emissions and Particulate Nitrate Formation in California. Abhishek Dhiman, Anikender Kumar, Maya Almaraz, Ian Faloona, Benjamin Houlton, MICHAEL KLEEMAN, *University of California, Davis*

PM2.5 concentrations in California continue to violate the National Ambient Air Quality Standards designed to protect human health. The highest PM2.5 concentrations occur during winter months with major contributions from particulate ammonium nitrate. Chemical transport models are used to help design efficient emissions control programs to address PM2.5 pollution, but these models have generally failed to predict basecase particulate ammonium nitrate concentrations in recent years. This calls into question the accuracy of future emissions control strategies for PM2.5 in California.

Recent work suggests that soils enriched with nitrogen fertilizers release oxides of nitrogen (NOx) that can play a role in atmospheric chemistry. Here we analyze the effect of soil NOx emissions on winter particulate nitrate formation and summer ozone formation in California. Monthly emissions of soil NOx are estimated based on fertilizer application rates, soil types, soil moisture, and temperature. These emissions are combined with standard emissions inventories provided by the California Air Resources Board. Episodes spanning the years 2000 through 2016 are simulated with and without soil NOx emissions using a regional chemical transport model. Predicted concentrations are compared to measurements to quantify improvements to model performance. Source apportionment routines are used to predict soil NOx contributions to ambient PM2.5 concentrations. Public health impacts are quantified using established epidemiological findings to estimate the potential health effects of soil NOx emissions in California.

7AM.17

Characterization of an Ultra-low Flow-rate Hydrocyclone. HYUNWOO LEE, Youngjin Seo, *Kumoh national institute of technology*

Hydrocyclone is a device for separating particles by centrifugal force from water which is a working fluid. Because of its advantages such as real-time separation and no moving part in it, it is used in numerous applications such as classifying, solids separation and concentration, etc. The objective of this study is to numerically characterize the particle separation efficiency by changing the design of hydrocyclone that operates at flow-rate of 1 LPM. To do so, we changed the diameter of the vortex finder and the length of the conical section, etc. The specific gravity of the injected particles is 1.25. The numerical analysis results showed that 5 µm particles or larger could be separated 100%. In addition, separation efficiency became enhanced when the design of hydrocyclone was changed. For instance, the efficiency was improved as the diameter of the vortex finder was decreased, but the flow rate of the purified working fluid was decreased. We will also present experimental data using the optimized hydrocyclone.

7AM.18

Modeling the Dynamics of Fractal-Like Soot Aggregates Using the Specialized Aerosol Solver. VICTOR GRYAZIN, Sergey Beresnev, *Ural Federal University, Ekaterinburg, Russia*

Various applications of processes of radiation absorption and motion of soot particles are well-known under the numerous publications. Among them appreciable interest is caused by experimental and theoretical researches of the radiometric phenomena (thermo- and photophoresis) with carbonaceous aerosols well absorbing radiation practically in the all range of radiation wavelengths. Such investigations require numerous calculations; therefore specialized aerosol solver for a wide range of calculations related to the photophoretic motion of soot particles is developed. It is useful to keep the mathematical formalism used in model of homogeneous spheres (the general solution of fractal-like particle problem is extremely difficult).

The calculation of force and velocity of longitudinal radiometric photophoresis is based on the molecular-kinetic theory of this phenomenon (Beresnev et al, 1993). For calculations of optical characteristics for fractal-like particles it is possible to use methods of effective medium approximations (e.g., Chylek et al, 1988) and theoretical predictions for fractal-like soot particles by Mackowski (2006). It was revealed that the choice $m = 1.764+0.570i$ for $\lambda = 0.68$ µm (the wavelength of the He-Ne laser) is optimum. Effective thermal conductivity of fractal-like soot particles can be calculated using the method offered for estimation of thermal properties of nanofluids with significantly enhanced thermal conductivity by the aggregation of nanoparticles into clusters (Evans et al, 2008).

The determined above characteristics are used in gas-kinetic calculations for photophoretic force and velocity. Reliability and accuracy of suggested model is necessary to estimate by comparison with adequate experimental and theoretical data. The experimental results of Karasev et al (2004) on photophoretic velocities of soot particles in nitrogen provide a unique opportunity to compare results. In experiment two groups of aggregates sizes distinctly differ: small particles at $R_m \leq 0.5$ µm and large particles $R_m > 0.5$ µm for which the mobility radius R_m was defined by various techniques at invariable fractal dimension $D_f = 1.80$.

It is obvious, that for the quantitative description of fractal-like aggregates photophoresis it is necessary to have a strict theoretical method for prediction of parameter Λ on the basis of knowledge of fractal dimension of the aggregate D_f and thermal characteristics of primary particles.

The analysis has shown that for a qualitative and quantitative explanation of photophoretic motion of aggregates it is possible to apply the well-developed theory for homogeneous spherical particles at correct treatment of key parameters.

This work was supported by the Ministry of Education and Science of the Russian Federation through the base part of the State task for high educational institutions (the research project #2189).

Regional-scale Impacts of Primary Ultrafine Particle Emissions in the United States. BENJAMIN MURPHY, Francis Binkowski, Ekbordin Winijkul, Matthew Alvarado, *United States Environmental Protection Agency*

Direct particle emissions substantially increase ultrafine particle (UFP) concentrations near emission sources and have impacts on aerosol properties like bulk surface area. However, standard emission inventories like the National Emission Inventory (NEI) report only bulk coarse and fine particle mass emission factors and so most chemical transport models do not explicitly account for the impacts of the large magnitude of UFP number emissions. This gap has important implications for understanding and managing air quality in the U.S. with respect to particulate pollution.

We have updated the Community Multiscale Air Quality (CMAQ) model with new algorithms and data to investigate the contributions of specific emissions sectors to UFP concentrations throughout the US. This research version of the model, called CMAQ-UFP, includes improved parameterizations of aerosol emissions from a single-distribution approach to a rich dataset of multiple distributions with dependencies on emission source, technology, and fuel. The new model gives a more complete representation of the complexity of UFP sources, sinks, and potential impacts.

We apply the new model to specific observations made throughout the U.S. including California and the mountain west. This combination of sites allows us to evaluate the model against detailed in situ and remotely-sensed particle properties. It further allows us to characterize the model in urban/suburban regimes with dramatically varying contributions from individual sources. Finally, we use this platform to quantify the spatio-temporal variation in the contribution of primary/secondary sources to particle number and surface area, two metrics thought to be important for connecting particulate pollution to human health impacts. This exercise improves our understanding of the most effective ways to mitigate the highest UFP concentrations in the US.

7AM.20

Developing the SAPRC Gas-Phase Chemical Mechanism and Chamber-Based SOA Parameterizations for Evaluating Biomass-Burning Derived SOA from Furan and Furan Derivatives. JIA JIANG, William P. L. Carter, David R. Cocker III, Lindsay Hatch, Kelley Barsanti, *University of California, Riverside*

Biomass burning (BB) can release significant quantities of trace gases and particulate matter (PM) to the atmosphere, which will strongly influence climate and tropospheric air quality. Advances in analytical techniques have recently enabled improved identification and quantification of the gas-phase organic carbon emissions from BB. Efforts to quantify the potential secondary organic aerosol (SOA) formation from these recently identified compounds have been hindered due to the lack of published information on the reaction kinetics and mechanisms for atmospheric oxidation, as well as the lack of chamber-based SOA yields. Furan and its derivatives represent one significant class of compounds in BB emissions, for which the fate and potential role as SOA precursors remain largely unexplored.

Here we present recent developments in: 1) the SAPRC gas-phase chemical mechanism to treat the atmospheric oxidation of furan/furan derivatives; and 2) SOA parameterizations for furan/furan derivatives derived from existing chamber data. Prior to this study, the treatment of furan chemistry in SAPRC was highly condensed and parameterized, which made it less reliable for atmospheric predictions in BB-influenced regions. Reaction rates of furan/furan derivatives with atmospheric oxidants and subsequent product yields were updated based on published literature specific to furan/furan derivatives and structure-activity relationships; the mechanism, including recent updates, was designed to be applicable for both low and high NOx conditions. Smog chamber data from fifteen experiments with furan or its methyl derivatives were used to evaluate the SAPRC model with updated furan/furan derivative chemistry. Additionally, SOA parameterizations were derived by fitting measured SOA yields (wall-loss corrected) using a Volatility Basis Set (VBS) modeling approach. The updated gas phase and SOA modeling results will be presented. Together the updated SAPRC mechanism and chamber-based SOA parameterizations will allow predictions of the potential contribution of BB-derived furan and furan derivatives to SOA formation using chemical transport models. Future work will include additional chamber studies to investigate a wider range of furan derivatives and chemical conditions most relevant in fire-impacted regions. Modifications to the SOA parameterizations to better represent the range of formation processes will also be considered.

7AP.21

Evaluation and Comparison of Aerosol Properties at Two Background Sites in the Central Amazon Rainforest. MARCO AURÉLIO FRANCO, Luciana Rizzo, Paulo Artaxo, *University of São Paulo*

The Amazon rainforest is the largest tropical forest in the world and occupies approximately half of the Brazilian territory. Its huge ecosystem interacts directly with the atmosphere, making the forest a biogeochemical reactor with capacity of regulation of climatic processes on a continental scale. The Amazon is one of the few continental regions of the Earth where the atmosphere in the rainy season is considered in pristine conditions, allowing for detailed studies of natural processes that controls generation and influence of aerosols on climate. In particular two sites, ATTO and ZF2, are of great relevance in the study of background aerosols properties in the Central Amazon, both sites located upwind the pollution plume of the Manaus city. The ATTO and ZF2 sites are located 160 and 60 km from the city, respectively, both surrounded by undisturbed forests. Due to the proximity, it is possible that the ZF2 is occasionally affected by the Manaus plume.

In this study it was evaluated the distribution of natural aerosols at the ZF2 and ATTO sites based on their physico-chemical properties. The data used in this analyzes were taken simultaneously at the sites between 2014 and 2016 , including particle light scattering and absorption coefficients, number concentration, number size distribution and chemical composition with nephelometer, MultiAngle Absorption Photometry, Scanning Mobility Particle Sizer and Aerosol Chemical Speciation Monitor. The analysis showed that both in dry and rainy seasons the aerosol scattering coefficients at 525 nm has differences between the sites. In the dry season of 2014 there were two events, probably regional fires, one in August and another in September, in which the scattering coefficient reached values greater than 200 Mm^{-1} at the ZF2 site and 140 Mm^{-1} at the ATTO site, respectively. Analyzes of the single scattering albedo (SSA) in 637 nm using boxplots showed that the median value in August at the ATTO site was 0.81 and at the ZF2 site the median was 0.91.

In September, the median SSA in the ATTO site was 0.83, while at the ZF2 site the median SSA was 0.87, what indicate predominance of more light scattering particles in ZF2 site in comparison of those at the ATTO site. In the rainy season of 2014, other two aerosol events occurred in March and April, raised the scattering coefficient to approximately 60 Mm^{-1} at the ATTO site, while at the ZF2 site its values remained at approximately 40 Mm^{-1}.Analyzes of SSA in these months showed that in the ATTO site the median was 0.93 for both March and April, while in the ZF2 site the median was 0.81, showing predominance of light absorbing particles at the ZF2 site. Monthly boxplots for SSA showed opposite behaviors at both sites. While in the ZF2 the monthly median of SSA increases between January and August and decreases between October and December, in the ATTO there are very clear oscillations, with values of medians higher in the rainy season and lower in the dry season, with predominance of more light scattering particles at this site. Those results indicate unexpected inhomogeneity in the optical properties of the aerosols between both sites, and can be caused by the presence of different types of particles in both sites, probably by pollutants from Manaus that reach ZF2 site.

7AP.22

Mass Accommodation and the Condensation Rate for Nanoclusters. Huan Yang, Eirini Goudeli, CHRISTOPHER HOGAN JR., *University of Minnesota*

In modeling particle growth in the gas phase, the condensation rate for nanoparticles is most commonly calculated with a hard-sphere derived equation, in which the condensation rate coefficient scales with the square root of the temperature (i.e. the free molecular condensation rate equation). However, molecular scale clustering reactions, in which two vapor molecules/atoms collide and bind to one another to form a condensed phase entity, often have rates which decrease with increasing temperature. As condensational growth proceeds from the molecular scale to the particle scale, the condensation rate coefficient therefore must undergo a shift from molecular scale behavior (decreasing with temperature) to particle scale behavior (increasing with temperature). Using molecular dynamics trajectory calculations combined with classical collision rate theory, we have examined the evolution of the condensation rate coefficient and the degree of mass accommodation (binding efficiency) for homogeneous condensation onto gold and magnesium nanoclusters (composed of 6-50 atoms). Interestingly we find that for each cluster, above a critical temperature, there is a transition in the condensation rate coefficient; below the critical temperature its derivative is positive with temperature, and above it its derivative with respect to temperature can become negative. Critical temperatures, particularly for the smallest clusters, are found to be well below the melting temperature of the cluster, and at the critical temperature clusters are still stable over the time scales of simulations. We additionally examine high speed atom-nanocluster collisions, which do not lead to binding/condensation, but instead lead to cluster dissociation.

7AP.23

Exploring the Room Temperature Sensing Mechanism of SnO2 Nano-Columns Synthesized by Aerosol Routes towards Volatile Organic Compounds: Theoretical Calculations Compared to Experimental Results. AHMED A. ABOKIFA, Kelsey Haddad, John Fortner, Pratim Biswas, *Washington University in St Louis*

SnO_2 is a wide bandgap semiconducting metal oxide that has been broadly employed as the active sensing material in chemiresitive gas sensors. Recent studies demonstrated the capability of bare-SnO_2 sensors to detect various gases, including volatile organic compounds (VOCs), at room temperature. To explore the sensing mechanism, the adsorption of ethanol and acetone on the (110) and (101) surface facets of rutile SnO_2 is investigated via density functional theory (DFT) calculations and *ab-initio* molecular dynamics (AIMD) simulations. The role of surface oxygen defects, polarity of the VOC molecule, and pre-adsorbed oxygen species from the ambient atmosphere is explored. Theoretical calculations are supplemented by sensing measurements for ethanol using SnO_2 nanostructured thin film sensors fabricated by an aerosol chemical vapor deposition (ACVD) technique.

DFT results show that the direct adsorption of both ethanol and acetone on the (110) and the (101) surface facets of SnO_2 is energetically favorable. The adsorption of both molecules is accompanied by the release of charge from the adsorbate gas to the surface, which promotes the sensing response. Binding strength of both molecules on the stoichiometric (110) and (101) surfaces is greater than that on the oxygen defective surfaces. Ethanol adsorption is generally stronger than acetone due to the bipolar nature of the hydroxyl (OH) group that interacts with the surface via two distinct charge transfer modes. To date, the most cited model regarding the sensing mechanism of metal oxide chemiresistive sensors is through the interaction with the ionosorbed (O^-) species that possess high activity towards oxidizing target gas molecules. However, at room temperature, the less active superoxide molecules (O_2^-) constitute the majority of the pre-adsorbed oxygen species on the SnO_2 surface. DFT results show that minimal interaction takes place between the pre-adsorbed oxygen species (O_2^-) and the studied polar VOCs upon their adsorption on the reduced surfaces. Taken together, these results suggest that the sensing mechanism of SnO_2 towards polar VOCs at room temperature can be explained by their direct adsorption on the surface rather than through their oxidation by means of ionosorbed oxygen species.

Nucleation and Growth of Iodic Particles in the CERN CLOUD Experiment. XUCHENG HE, Lubna Dada, Siddharth Iyer, Hanna Manninen, Yee Jun Tham, Joao Almeida, Dexian Chen, Dominik Stolzenburg, Changhyuk Kim, Arttu Ylisirniö, Maija Peltola, Theodore Koenig, Henning Finkenzeller, Mario Simon, Andrea Baccarini, Richard Flagan, Neil Donahue, Siegfried Schobesberger, Katrianne Lehtipalo, Rainer Volkamer, Douglas Worsnop, Matti Rissanen, Markku Kulmala, Jasper Kirkby, Mikko Sipilä, *University of Helsinki*

Trace iodic vapours have a significant impact on atmospheric chemistry, influencing catalytic ozone destruction and the HOx and NOx cycles. Oxidised iodine species also form aerosols in coastal and polar regions [1], so they play a direct role in Earth's radiation balance. It was recently shown that iodic acid (HIO_3) forms new particles in coastal and polar regions [2] but the chemical pathways leading to HIO_3, and the nucleation and growth rates of iodic particles, remain poorly understood.

In a comprehensive series of experiments performed under atmospheric conditions in the CLOUD chamber [3] at CERN, we have investigated how the precursor vapours iodine and diiodomethane are oxidized to HIO_3; we have also measured the resulting nucleation and growth rates of iodic particles. Surprisingly, we found that HIO_3 forms over a range of relative humidity via a previously-unknown mechanism. We have combined our laboratory experiments with quantum chemical calculations to resolve the exact chemical steps leading to the formation of HIO_3 in the atmosphere.

A bromide chemical ionization time of flight mass spectrometer was used to measure the concentration of molecular iodine at atmospheric concentrations while simultaneously measuring iodic acids and oxides for the first time. This instrument enabled us to comprehensively track the role of individual iodine species in the gas-phase chemistry and nucleation processes.

We have measured the nucleation and growth rates of pure iodic particles. By comparing experiments under neutral (ion-free) and GCR (galactic cosmic ray) conditions [3], we find an important contribution of ions to the nucleation and initial growth rates. Using a suite of state-of-the-art high-resolution instruments, we were able to follow the appearance and growth of iodic particles from an HIO_3 dimer to sizes above 10nm, with chemical identification throughout the entire size range. The data reveal that several growth mechanisms are involved, depending on the particle size.

Our laboratory findings should help to interpret observations of new particle formation in coastal and other regions in the presence of gas-phase iodic species. And the results indicate there are unrevealed oxidation pathways that can affect the fate of ozone in the atmosphere.

Simulations of Light Scattering from Aligned and Randomly Oriented Polydisperse Aggregates for Determining Aggregate Shape.

GEORGE MULHOLLAND, James Corson, Michael Zachariah, *University of Maryland*

This study focuses on the simulation of the light scattered by aligned and randomly oriented fractal aggregates of touching spheres. We find from the simulations that a shape parameter for a population of aggregates can be determined from these scattering calculations. The dependence of the structure factor, *S*, on the magnitude of the scattering wave vector, *q*, has been an important tool in the study of the size, the fractal dimension, and the pair distribution function for randomly oriented aggregates. However, such measurements do not provide a measurement of the shape of the aggregate. As discussed in a previous paper (Mulholland, G.W. et al., 2013), an aggregate aligned by an electric field in the direction of the largest principal radii of gyration will scatter more intensely in the forward direction than in other orientations because there is less destructive interference. The scattering plane is oriented perpendicular to the electric field. This paper also showed that a ratio of slopes computed from small angle light scattering intensities is related to the shape parameter A_{31}, which is the ratio of the largest to the smallest principle radii of gyration of the inertia tensor. This measure of shape anisotropy may be an important property regarding the transport of the aggregates, the aggregation rate, the collection efficiency by a filter, and for the characteristics of manufactured aggregates. Since A_{31} is unity for a sphere, a measurement of A_{31} can also be a sensitive diagnostic for the presence of aggregates in an aerosol such as an atmospheric cloud.

In the present study, aggregates were generated to simulate the range of aggregate sizes (30 to 2000), primary sphere radii (10 nm – 23 nm), and size distributions for soot from buoyant turbulent flames at long residence times for a range of hydrocarbon fuels(Koylu, U.O.et al., 1992). More nearly monodisperse aggregates were also generated to simulate the size distributions obtained via mobility or mass classification. The aggregates were generated for a fractal dimension characteristic of classical diffusion–limited cluster-cluster aggregation (DLCA) using an algorithm developed by Mackowski (2006). The value of $S(q)$ was computed for the aligned (but free to rotate about the alignment axis) and randomly oriented clusters. The aggregates were aligned by the electric field in the direction yielding the minimum energy associated with the polarizability of the aggregate. This direction was computed using an algorithm developed by Mansfield et al. (2001).

Results on the correlation between the ratio $\{S(q)\}_a / \{S(q)\}_r$ for the monodisperse and polydisperse clusters and the average value of A_{31} indicate that light scattering measurements in the q range of fractal behavior would be feasible for shape characterization. Also for small q (Guinier regime), the strong correlation between A_{31} and the ratio of slopes of $S(q)^{-1}$ vs. q^2 previously obtained for single aggregate simulations is also valid for polydisperse aggregates. This suggests that small angle light scattering measurements would provide shape information.

The fundamental differences in the light scattering and the pair correlation function for the aligned and randomly oriented clusters will also be discussed.

Spreading Ratios for Aqueous to Glassy Aerosol Particles Using Atomic Force Microscopy (AFM). ZIYING LEI, Nicole Olson, Rebecca Craig, Andrew Ault, *University of Michigan*

The viscosity of atmospheric aerosol particles is a fundamental property that impacts heterogeneous chemistry, phase transitions, and hygroscopicity. Viscosity can be related to the spreading ratio of impacted particles through viscoelastic properties. Particle size, chemical composition, and relative humidity (RH) all affect viscosity, and need to be accounted for when determining and predicting aerosol particle spreading ratios after impaction. However, the viscosity of atmospheric particles is currently poorly quantified, and understanding of spreading ratios from aqueous to glassy aerosol particles is still incomplete. This study aims to determine the relationship between spreading ratio and viscosity of standard aerosol particles composed of inorganic and organic standards. To determine spreading ratio as a function of particle size and RH, laboratory experiments were conducted on size-selected particles (50 – 1,000 nm) under a range of RH conditions (10 – 90%). Atomic force microscopy (AFM) was used to characterize the morphology, height, and projected area diameter of particles, from which the spreading ratio was calculated for individual particles. Changes in spreading ratios were observed with increasing aerosol particle size, as well as with decreasing RH. A fundamental understanding of spreading ratios is will provide insight into the viscosity of aqueous to glassy aerosol particles, which has important implications for water uptake and heterogeneous reactivity.

Characterizing Mass-resolved Mixing State of Black Carbon in Beijing Using Morphology-Independent Measurement Method. CHENJIE YU, Dantong Liu, Kurtis Broda, Rutambhara Joshi, Jason S. Olfert, Hugh Coe, James Allan, *University of Manchester*

The mixing state of black carbon (BC) significantly determines its absorbing efficiency and may modify its regional and global radiative forcing impact and may also influence toxicology. Here, with the aim of identifying the mixing state of BC, an experiment was devised as part of a large joint UK-China project investigating air quality in Beijing, Air Pollution and Human Health-Beijing (APHH-Beijing). During this experiment, we successfully applied a morphology-independent mass measurement of BC for intensive measurements in both winter and summer. We directly selected the particle mass using a Centrifugal Particle Mass Analyser (CPMA, Cambustion Ltd) and passed these monodisperse particles to a single particle soot photometer (SP2, DMT inc.) to characterize refractory BC mass for each single BC-containing particle. The coupling of CPMA-SP2 can thus quantify the mixing state of BC without assuming any particle morphology. The CPMA-SP2 results have been applied to a recently published inversion algorithm to derive the full distributions of particle number according to total mass and rBC mass. Such detailed mass-resolved BC mixing information could be used as optical model input to estimate the optical properties, and also the micro-scale processing model to investigate the atmospheric processing of BC.

7AP.29

New Insight Into Arctic Atmospheric Aerosol Formation. LISA BECK, Clemence Rose, Ella-Maria Duplissy, Matthieu Riva, Federico Bianchi, Olga Garmash, Heikki Junninen, Clara Hoppe, Alexander Schulz, Viola Angelo, Vitto Vitale, Mauro Mazzola, David Cappelletti, Markku Kulmala, Veli-Matti Kerminen, Mikko Sipilä, *University of Helsinki*

Particle formation is globally contributing approximately 50% of cloud condensation nuclei. With increasing temperature, the emission of gases from the different spheres, like hydrosphere, biosphere but also the fauna, is changing; consequently, the molecular composition of the atmosphere is changing. To understand the extent to which the temperature rise and sea ice loss may contribute to future cloud formation and radiation feedback, we must know the mechanisms of particle formation. Therefore, we conducted a field campaign from March to August 2017 in Ny Ålesund, Svalbard at 79° N. Mass spectrometers were among the key instrumentation for solving the molecular mechanism of particle formation. In our campaign, we were able to solve the role of sulfuric acid, ammonia, amines, iodic acid, methane sulfonic acid, highly oxidized organic molecules as well as ions in new particle formation. To understand the effect of changing temperature on particle formation requires accounting for all different spheres. Based on our results, for example, we expect that changes in phytoplankton phenology and sea ice extent will greatly affect aerosol formation in those regions. This study aims to combine all the components related to gas-to-particle conversion necessary for predicting future behaviour of arctic clouds and climate.

7AP.30

Contrasting Physical Properties of Black Carbon in Urban Beijing between Winter and Summer. DANTONG LIU, Rutambhara Joshi, Chenjie Yu, James Allan, Hugh Coe, Michael Flynn, Junfeng Wang, Xinlei Ge, Yele Sun, Pingqing Fu, *University of Manchester*

Black carbon (BC) exerts both climatic and health impacts, especially in regional hot spots with high emissions. The populated megacity represents the most complex anthropogenic BC emissions where the sources and related impacts are very uncertain. This study provides a characterization of BC in the Beijing urban environment using single particle soot photometry during the joint UK-China APHH (Air Pollution and Human Health) project, in both winter (Nov. - Dec. 2016) and summer (May - Jun. 2017). During this experiment, we successfully gathered 4 weeks of continuous measurements for each season, including several severe pollution events in Beijing. The BC was found to have contrasting physical properties between both seasons. In winter, during periods of high pollution levels, the core sizes of BC were larger and the coatings were thicker; whereas in summer at the same level of pollution, core size of BC particles showed little variation and the coatings were lower than in winter. This phenomenon may result from a more significant contribution of BC from the residential emission sector in winter, but may be also modulated by local and synoptic meteorology. By measuring the BC physical properties in single particles, we separate four modes of BC with different size-resolved mixing state. By comparing these modes of BC with source apportionment results based on chemical composition analysis using soot particle mass spectrometry, we are able to link the separated BC modes with possible emission sources. This paper will examine the behaviour and contribution of BC with contrasting physical properties in both seasons and will link this to the optical properties to evaluate the possible mass contribution and optical budgets of BC among different emission sectors in Beijing.

7AP.31

Theory for the Glory. Extensions of the Surface Wave Mechanism. CHEYNE WEIS, Christopher Sorensen, *Kansas State University*

The optical phenomena of the glory has been explained in terms of the interference of beams emanating from surface waves from diametrically opposite sides of a spherical particle. This explanation clearly predicts a linear correlation between phase angle of the first maximum in intensity nearest to the back direction and the size parameter. We find a limitation to the refractive indices where this surface wave mechanism is viable, and then demonstrate through the Mie Solution that the correlation continues outside this domain, and then gradually deviates as the refractive index increases. For these larger refractive indices we then give an alternative mechanism based on ray optics (with no surface waves) possible at refractive indices above the square root of two that predicts the same functionality. Our non-surface wave glory, while of interest in itself, might have use for explaining the enhanced scattering that occurs for many non-spherical particles that occur in nature.

7AP.32

Molecular Content of the Critical Clusters of Lower n-Alkanes: Experimental Characterization Using Mass Spectrometric Detection and Small Angle X-ray Scattering. KEHINDE OGUNRONBI, Martina Lippe, Ruth Signorell, Barbara Wyslouzil, *The Ohio State University*

Understanding the vapor to liquid phase transition of n-alkanes is motivated by both technological and fundamental considerations. On the one hand, separation processes that recover natural gas liquid (NGL) from raw natural gas streams often involve expanding and cooling the natural gas stream across Joule-Thompson throttling valves, turbo-expanders, or supersonic nozzles. In all cases, vapor phase nucleation initiates condensation of the longer chain length alkanes. On the other hand, the simplicity of the interactions between n-alkane molecules makes them interesting candidates for both fundamental experimental and simulation studies.

In this work, we investigate the vapor-liquid nucleation of lower n-alkanes – pentane, hexane, and heptane – on the microsecond timescale in supersonic Laval nozzles and report the critical cluster sizes of droplets formed in the nozzles. We characterize the expanding gas mixture flow inside the nozzle using pressure trace measurements (PTM) and characterize the aerosols generated in the nozzle using small angle x-ray scattering (SAXS). Analyzing the SAXS and PTM data from different nozzles, characterized by different expansion rates, yields the supersaturation dependence of the nucleation rate, from which we determine the critical cluster sizes using the first nucleation theorem. The results from this conventional approach are compared with the results of directly characterizing the clusters in a uniform post-supersonic nozzle flow using mass spectrometric detection and soft single-photon by vacuum ultraviolet (VUV) light.

7AP.33

Errors in Nanoparticle Growth Rates Inferred from Measurements in Chemically Reacting Aerosol Systems. CHENXI LI, Peter H. McMurry, *University of Minnesota*

In systems where aerosols are being formed by chemical transformations, individual particles grow due to the addition of molecular species. Other processes, such as coagulation, may also lead to particle growth, but coagulation is a well understood process that is described by the coagulation integrals in the aerosol general dynamics equation. Growth, in contrast, is not always sufficiently well understood to be accurately described in models, especially for chemically complex systems such as the atmosphere. Processes including condensation & evaporation, acid-base reactions, organic salt formation, liquid phase reactions, and the accretion of two or more organic molecules to form a larger compound having lower volatility may contribute to growth. Efforts to improve our understanding of growth due to chemical transformations often focus on attempts to reconcile observed growth rates with values calculated from models.

However, because it is typically not possible to measure the growth rates of individual particles in chemically reacting systems, they must be inferred from measurements of aerosol properties such as size distributions, particle number concentrations, etc. For example, atmospheric nucleation leads to the formation and growth of a nucleation mode. Growth rates are sometimes assumed equal to the growth rate of the geometric mean size of this mode. However, this modal growth rate is also affected by self-coagulation of particles within the mode as well as condensation of smaller molecular clusters that are often not measured. To determine growth rates from such observations, it would be necessary to correct for the effects of coagulation on modal size. This complicates data analysis procedures and may require information that was not measured or is otherwise unknown for the system under study.

This presentation quantifies errors in growth rates obtained using methods that are commonly employed for analyzing atmospheric data. We analyze "data" obtained by simulating the formation of aerosols in a system where a single chemical species is formed at a constant rate, R. The advantage of this approach is that we understand the system perfectly, so can unambiguously determine true particle growth rates, which are due solely to condensation and evaporation. We examine the effects of a pre-existing aerosol and of evaporation. We show that the maximum possible error in measured growth rates occurs for collision-controlled nucleation in a single-component system in the absence of a pre-existing aerosol, wall losses, evaporation or dilution, as this leads to the highest concentrations of nucleated particles. Those high concentrations lead to high coagulation rates that cause the nucleation mode to grow faster than would be caused by vapor condensation alone. Scavenging by preexisting aerosol, wall losses, evaporation and dilution decrease concentrations of nucleated particles, thereby decreasing errors associated with coagulation. Although we do not explicitly study the effects of growth pathways other than condensation (i.e., contributions to growth by other chemical species or processes), they would lead to higher growth rates and therefore smaller relative errors in growth rates due to coagulation.

Our analysis is based on the non-dimensional formulation described by McMurry and Li (2017). This allows us to draw general conclusions that are independent of the chemical species and of the rate of aerosol formation. We show that for collision-controlled nucleation, the modal growth rate can be up to a factor of five higher than the true growth rate.

7AP.34

Fractal Scaling of Soot Packing density Across Five Size Decades. PAI LIU, William Heinson, Rajan K. Chakrabarty, *Washington University in St. Louis*

Fractal aggregates in nature grow with a scaling dimensionality less than the spatial dimension. This results in their packing density (ϑ_f)–defined as the fraction of volume occupied by solid component–decreasing with increasing size R_g/a (aggregate radius of gyration normalized by average monomer radius). Fundamental questions remain regarding the scaling laws and physical mechanisms controlling the evolution of ϑ_f for the aggregates produced from combustion systems, especially after the onset of gelation. Here, we experimentally map the scaling of ϑ_f for soot aggregates across five orders of magnitude of R_g/a. The ϑ_f-R_g/a scaling relationship evolves through three successive regimes with distinct power-law exponents of -1.20±0.01, -0.58±0.06, and -1.31±0.14. The first cross-over agrees with the classical aerosol-to-gel transition theory. This agreement, however, breaks down at the second cross-over point, where a late-stage cluster-cluster aggregation of gel particles takes over.

7AP.36

Can Nanodroplets Shatter? YENSIL PARK, Kehinde Ogunronbi, Barbara Wyslouzil, *The Ohio State University*

Millimeter and micron size water droplets that freeze from the surface inward can build up enough internal pressure, due to the density mismatch, to explode. In our freezing experiment of n-alkane nanodroplets, we occasionally observe droplets that shrink far more than they should based on the expected liquid/solid density change. Furthermore, at the low temperatures involved, mass loss by evaporation should be negligible, even if the droplets reach their melt temperature.

Data from n-hexane nanodroplets is particularly intriguing. Here, nanodroplets formed in a supersonic Laval nozzle by condensation and then froze. The particles and the phase transitions were characterized using pressure trace measurements (PTM), Small Angle X-ray Scattering (SAXS) and Fourier Transform Infrared Spectroscopy (FTIR). In one case the carrier gas was pure Argon and in a second case the gas mixture contained 12 % CO_2. In both cases we observed a sudden decrease in droplet size and a corresponding heat release event. In the Argon case, the average droplet radius decreased by ~ 7.5 %, and in the presence of CO_2 the decrease was ~ 17.0 %. FTIR clearly confirms freezing in the pure Ar case, but not when CO_2 is present. Since n-alkanes are known to freeze from the surface inward if the chain length is long enough, it may be possible that gasses expelled from the crystal structure exert enough pressure to shatter these droplets despite their small size.

7AP.37

Hybrid Fractality and Formation Mechanism of Aerosol Gels. YULI W. HEINSON, William Heinson, Pai Liu, Rajan K. Chakrabarty, *Washington University in Saint Louis*

Aerosol gels are volume spanning, semi-rigid networks of solid nanoparticles possessing ultralow density and high surface area. The current consensus is that aerosol gels have a hybrid morphology with a mass (D) and surface (D_s) fractal dimension ~ 2.5 at super-micron length scale and ~ 1.8 at submicron length scale. In this study, we show that this consensus is partially complete and is not universal. Using our light scattering apparatus, we studied the structure factor of carbon aerosol gels produced using a buoyancy-opposed flame (BoF) aerosol reactor which facilitates continuous aerogelation on a millisecond time-frame. Our light scattering apparatus measured the scattered intensity by the gel particles in the scattering angle range of 1˚ ~ 168˚. We were able to probe the hybrid morphology by plotting the scattering intensity versus q, where $q=4\pi/\lambda \sin(\theta/2)$ with λ the wavelength and θ the scattering angle. Our light scattering results indicate that aerosol gel particles produced from our BoF reactor process a $D \approx 2.5$ and a $D_s \approx 2$. This surprising, yet previously undescribed morphology was further investigated for a convincing explanation using numerical simulation of diffusion limited cluster-cluster aggregates under varying monomer volume fraction conditions. This talk will present in detail our experimental findings and modeling interpretations.

7AP.38

Relationships between Scattering Directionality Parameters for Fractal Black Carbon Aerosols. APOORVA PANDEY, Rajan K. Chakrabarty, *Washington University in St Louis*

The magnitude of aerosol direct radiative forcing effect is significantly affected by the angular distribution of aerosol light scattering. In radiative transfer schemes, this distribution is typically condensed into single-valued parameters. An analytical expression known as the Henyey-Greenstein (HG) phase function is widely used to connect three single parameter representations of aerosol scattering directionality: the hemispherical upscatter fraction (β), the backscatter fraction (b), and the asymmetry parameter (g). The HG phase function does not take particle morphology into account, which could lead to significant errors for non-spherical particles. We calculated these single parameters for fractal black carbon (BC) aerosols using the numerically exact superposition T-matrix method. Here, we illustrate the effect of particle size and morphology on β, g and b for single particles. We developed empirical equations to capture the relationships between these parameters. For a known value of b, which can be obtained through direct measurement, the errors in β and g estimated using the HG phase function could be up to 35%. However, the large mass absorption cross-section of BC aerosols dominates their radiative forcing effect. Therefore, the rather large errors in scattering directionality result in ≤8% error in BC direct forcing efficiency at 550 nm wavelength.

7AP.39

Urban Aerosol Size and Concentration: Characterization in a Light Industrial Area 2017/2018 Compared to 2005.

TORSTEN TRITSCHER, Thomas Krinke, Axel Zerrath, Oliver F. Bischof, *TSI GmbH*

The particle size distribution of urban aerosols is typically dominated by ultrafine particles (UFP) originating from local sources such as traffic and industrial emissions. Due to their negligible mass they are clearly underrepresented by legislative PM10 mass measurements. This is one reason why the UFP contribution to urban air quality is better characterized by their number size distribution and particle number concentration.

In 2005 we carried out an initial study of the physical properties of the urban aerosol in a light industrial area in the city of Aachen, Germany (Bischof & Zerrath, AAAR 2005). The sampling location was near a freeway and in close proximity to two bus depots operating the local public transport network. We chose to repeat that study 12 years after the original campaign as the larger of the two bus companies frequently made upgrades to their bus fleet. This change in one of the predominant local emission sources should be notable in urban air quality improvements when comparing our latest measurements to the 2005 results. One interesting additional fact is that the city of Aachen introduced a low emission zone (LEZ) in February 2016. Other studies have shown (TROPOS, 2017) that improvements in air quality due to LEZ's are not well reflected when only considering PM10, while UFP measurements easily show reductions well in double digit values.

During both studies the sampling site was located at an identical distance of 50 m from the road and 200 m from the freeway. The depot of the public transport company and the lots of the private bus depot remained in their locations. Both result in extended bus traffic passing by the sampling location in particular in the mornings and afternoons of weekdays. We used a complete sampling system with PM10 head, PM1 cyclone, Nafion dryer and flow splitter in order to condition the ambient air aerosol and allow the connection of a wide choice of instruments.

An Ultrafine Particle Monitor (UFP, TSI Model 3031) was used to measure the particle number size distribution in 6 size fractions ranging from 20 to 800 nm. The UFP monitor was complimented by a high-resolution SMPS (TSI Model 3938) during selected periods. In addition we operated two models Condensation Particle Counters (CPC): a butanol-based monitoring CPC that fully complies with the CEN/TS 16976 specifications (TSI Model 3772-CEN) and a water-based instrument (WCPC, TSI Model 3788).

For the duration of the 2005 measurements the particle number concentration was typically below 5,000 particles/cm^3 at night time but exceeded values of 10,000 particles/cm^3 during day time with occasional peaks of up to 100,000 particles/cm^3. We found that these peaks correlated well with the bus fleet leaving from or arriving at the bus depot. Particle size distributions were dominated by particles below 200 nm in diameter and individual events with traffic revealed modal values of the distribution below 50 nm.

The influence of traffic remains clearly visible also in the 2017 data. Especially the morning peak when buses leave the depot showed a typical behavior, with the size distribution being dominated by particles smaller than 70 nm. The difference in total particle concentration between the UFP monitor and the CEN-CPC can be mainly attributed to the different lower cut-off size of 20 nm and 7 nm, respectively. We will present more detailed data, including measurements made during other months to complete the characterization of the urban aerosol at this site.

7AP.40

Glass Forming Properties of Secondary Organic Aerosol Tracers and Surrogates Examined by Thin Film Dielectric Relaxation Spectroscopy. YUE ZHANG, Shachi Katira, Jason Injae Jung, Peyton Spencer, Andrew Lee, Andrew Lambe, Wen Xu, Leonid Nichman, Manjula Canagaratna, Zhenfa Zhang, Avram Gold, John Jayne, Jason Surratt, Timothy Onasch, Douglas Worsnop, Paul Davidovits, David Chandler, Charles Kolb, *University of North Carolina at Chapel Hill*

Particulate matter (PM) has important effects on the climate, human health, and visibility. Field measurements from different parts of the world show organic components comprise more than half of the total PM mass loadings. Recent studies have shown that some organic particles can transform from a liquid/semi-solid phase state to a glassy phase state as temperature, humidity, and composition change. Glass transitions from liquid/semi-solid to solid phase states have important implications for reactivity, growth, and cloud formation (cloud condensation nuclei and ice nuclei) capabilities of secondary organic aerosols. Glassy particles are less likely to undergo heterogeneous reactions, thereby inhibiting particle growth due to the slow diffusion rates of surface reactants. Glassy particles are also more prone to form ice crystals, thus favoring cirrus clouds, compared with non-glassy particles.

The small size and relatively low mass concentration of SOA in the atmosphere make it difficult to monitor atmospheric SOA glass transitions using conventional methods. To circumvent these difficulties, we have adopted a new technique for measuring glass forming properties of atmospherically relevant organic aerosols. Aerosol particles to be studied are electrostatically deposited in the form of a thin film onto a quartz surface with interdigitated electrodes. The thin films were then analyzed by dielectric spectroscopy, which provides dipole relaxation information related to the motion of the molecules as a function of temperature (373 to 233K) at atmospherically relevant cooling rates. The glass transition temperatures (T_g) of organic aerosol components (glycerol and citric acid) are obtained using this technique, and the results agree well with available literature data.

The glass transition temperatures of isoprene SOA components, including isoprene-derived epoxydiols (IEPOX) and 2-methyltetrols, were measured at three atmospherically relevant cooling rates, 2 K/min, 5K/min, and 10 K/min. The glass transition temperatures of these two compounds range from 162-166 K and 240-245 K, respectively. The results indicate that increasing the cooling rate can reduce the glass transition temperatures of isoprene SOA tracers by 4-5 K. This temperature difference corresponds to an 800-meter height in the ambient atmosphere for the corresponding updraft induced cooling rates. These results underscore the importance of atmospheric variables (such as updraft rates) of organic particles on their phase state and subsequent multiphase reactivity and cloud formation properties.

The glass transition temperatures of water-organic binary mixtures were measured as five mixing ratios. The Gordon-Taylor equation is applied to fit the glass transition temperatures of the mixture, where 136 K is the T_g of pure water. The parameterization of the Gordon-Taylor equation is applied to calculate the effect of relative humidity (RH) and water content on the glass transition temperature of organic aerosols, assuming a growth factor of 1.2 at 90% RH. The glass transition temperature of organic aerosols drops by 15-20 K as the relative humidity changes from <5% to 90%.

In summary, the data obtained with broadband dielectric spectroscopy can be used to characterize glass transitions for both simulated and ambient organic aerosols. The glass transition temperatures of organic aerosols as a function of water content and cooling rates are derived, and their climate effects are interpreted.

7BA.1

Microbial Population Structure in Aerosols from Near-ground during Fog–haze Days in Northern China. YUNPING HAN, Mengzhu Zhang, Lin Li, Junxin Liu, *Chinese Academy of Sciences*

Fog–haze events exhibit an episodic tendency in China. Aerosol particles during fog–haze days can affect human health and cause several diseases, particularly respiratory diseases. As such, the properties of aerosols and their microbial composition have been extensively investigated. The microbial properties of aerosols from near-ground are of different states under various weather conditions. However, microbial populations in aerosols from human breathing height under special weather conditions, such as fog–haze days, have been rarely examined. In our study, microbial populations in aerosols from near-ground (1.5 and 20 m) were investigated. Aerosols were sampled during and after fog–haze days.

All aerosol samples were consecutively collected at 1.5 m (breathing height) and 20 m (height of no surrounding obstacles) above ground during and after fog-haze days in northern China (116.34° E, 40.0 1° N). An impingement airborne microorganism sampler (SKC BioSampler, SKC Inc. USA) was used to collect aerosols. Clone library was used to analyzed microbial population.

A total of 400 sequences for bacteria and 200 sequences for fungi were obtained. After alignment was completed, 7, 2, 22, and 15 OTUs were identified in HYP-FZB20, HYP-FZB1.5, HYP-CB20, and HYP-CB1.5 clone libraries, respectively, and 7, 13, 1, and 4 OTUs were determined in the 50 screened fungal clones from HYP-FZF20, HYP-FZF1.5, HYP-CF20, and HYP-CF1.5 clone libraries, respectively. Coverage analysis indicated that the aerosol libraries represented approximately 83.00%–99.00% of the total number of the examined clones. Thus, a dependable inventory of bacterial 16S rRNA and fungal 18S rRNA gene sequences present in aerosols is provided.

Results showed that the bacterial diversity in aerosols during fog–haze days was lower than that after fog–haze days. Proteobacteria alone and Proteobacteria with Firmicutes were respectively detected in aerosols at 1.5 and 20 m during fog–haze days. In addition to Proteobacteria and Firmicutes, Bacteroidetes alone and Acidobacteria with Verrucomicrobia were respectively found in aerosols at 20 and 1.5 m after fog–haze days. The fungal species observed during fog–haze days were completely different from those detected after fog–haze days. Ascomycota and Basidiomycota were respectively detected during and after fog–haze days. The distribution of microbial diversity in aerosols exhibited meteorological and site-associated variations. The same potential pathogenic microorganisms were detected at different heights during fog–haze days. This study on the characteristics of microbial population in aerosols could provide a comprehensive understanding of the factors causing the harmful effects of particles on humans during fog–haze days.

7BA.3

SenseNet Bioaerosol Collector Development. DAVID ALBURTY, Zachary Packingham, Andrew Page, Steven Graham, Ann Packingham, *InnovaPrep LLC*

DHS has begun development of an indoor systems approach to a high-performing but low-cost indoor environmental monitoring for bioaerosol threats. The intent is to overcome cost barriers to the deployment of a widespread commercial and government network of monitoring devices. These systems will provide early warning for critical infrastructure such as convention centers, office buildings, mass transit centers, sports venues and other areas. The system development approach considers the technical challenges of sensor placement through a modeling approach, and uses a triggered aerosol collector. The collector operates at 200 LPM and the sample is captured on a dry electret filter tape. A prototype system was developed and a demonstration test was conducted using Barcode Btk endospores. Following capture, the spores are eluted from the filter by a carbonated surfactant buffer solution termed Wet Foam Elution™. The expanded wet foam efficiently elutes particles from the filter and then quickly collapses into two mL of flat liquid. The collector system pulls a measured quantity of sample fluid from 35 µL to one mL from the sample and transfers it through a standard Luer lock interface to a PCR identifier that is networked to the overall system for an alarm decision and response. The design and development of the automated low cost per sample bioaerosol collector and the technical demonstration aerosol chamber testing will be presented.

Optical Trapping-Raman Spectroscopy (OT-RS) for Concurrent Characterization and Monitoring of Physical and Chemical Properties of Single Airborne Particles. ZHIYONG GONG, Yong-Le Pan, Gorden Videen, Chuji Wang, *Mississippi State University*

The study of physical and chemical properties of a microscopic object, such as a single particle, is made possible using optical trapping (OT) technology combined with other measuring techniques. Here we show a universal optical trap combined with Raman spectroscopy (RS) and microscopy imaging for single-particle studies. The universal optical trap is constructed using two counter-propagating hollow beams and is able to stably levitate single particles of a wide range of properties, such as transparent or absorbing materials, organic (polymers, bioaerosols, etc.) or inorganic constituents (carbon, silica, glass, etc.), and spherical or irregularly shaped morphologies. Both physical and chemical properties and their temporal evolution of the trapped particle can be characterized simultaneously using the integrated OT-RS and imaging system. We created three sample cases to demonstrate the analytical merits of the system: (I) a single particle with no change, (II) partially degraded over the measuring period, and (III) one part from the fragmentized single particle. The particles' chemical compositions, crystalline states, etc. are inferred from their Raman spectra, while their physical properties (sizes, shapes, morphologies, etc.) are revealed by images. This integrated OT-RS system provides a new approach to concurrently characterize and monitor physical and chemical properties of single micrometer-sized objects optically trapped in air.

7BA.6

Two-Step Laser Desorption/Ionization Mass Spectrometry of Individual Microorganisms by Single Particle Aerosol Mass Spectrometry (SPAMS). DAVID FERGENSON, Sean Kinahan, Joshua Santarpia, *Livermore Instruments Inc.*

A Single Particle Aerosol Mass Spectrometer (SPAMS) was used to generate real-time mass spectrometric data acquired from individual aerosolized non-pathogenic microorganism particles, analyzed by infrared desorption followed by ultraviolet ionization.

SPAMS is a technology whereby individual aerosol particles are analyzed in real-time, with a dual polarity mass spectrum acquired along with the aerodynamic diameter of each particle. This SPAMS is distinct from predecessor instruments in its simplicity, its ability to operate under high aerosol concentrations, and the number of aerosol particles that it can analyze per second. A SPAMS instrument is maintained under vacuum and aerosol particles are driven into its differentially pumped interface by atmospheric pressure. An aerodynamic focusing lens stack focuses the particles into a beam assuring that they arrive at the center of the source region of a dual polarity time-of-flight mass spectrometer. A single continuous-wave laser that is square in profile is oriented across the aerosol beam so that, when a particle crosses it, light scattered from that particle is detected by a photomultiplier tube. The duration of the light scattering indicates the velocity of the particle which is related to its aerodynamic diameter.

In a conventional SPAMS instrument, as the particle exits the laser, the cessation of detected scattered light is used to actuate a pulsed ultraviolet laser which is focused just below the scattering laser. The pulsed laser desorbs material from the particle and ionizes the material, with resulting ions analyzed by the mass spectrometers. Previous experiments involving the analysis of individual aerosolized microorganisms by SPAMS have demonstrated the technique's ability to discern genera and, in some cases, species across different growth conditions. However, the information available in the mass spectra was limited by the fragmentation of the molecules by the harshness of the desorption process. Several predecessor instruments to the SPAMS were modified with an alternate desorption/ionization process whereby the individual particles were first desorbed into the vapor phase by a CO_2 laser and then ionized using an ultraviolet laser in a second step, preserving molecular ion information intact. In this work, a SPAMS instrument was fitted with a 2-step desorption/ionization scheme and applied to the analysis of individual microorganisms.

7BA.7

Pathogenic Bioaerosol Detection in Under 30 Minutes. Robert Ferguson, Corinne Whitby, Dumbrell Alex, IAN COLBECK, *University of Essex, Colchester, CO4 3SQ, UK*

Deleterious health effects can arise following exposure to infective airborne microorganisms (bioaerosols). However, the risk of human exposure to bioaerosols remains difficult to quantify in real time. Currently, regulators rely on culture-based methods targeting only a single pathogen (i.e. *Aspergillus fumigatus*) as the industry's 'gold' standard. Such approaches are labour and time intensive, taking days to produce results. As the vast majority of microorganisms cannot be cultured these methods underestimate microbial loadings and key pathogens that may also be present are routinely overlooked. We present a tool for detection of specific bioaerosol pathogens in the field in less than 30 minutes.

Our method is based on isothermal amplification (LAMP) of DNA. LAMP is ideal for pathogen detection as it can identify one copy of a specific gene target in less than an hour [1]. The time from sample collection to result is under 30 minutes. We can achieve this as the result is shown by a colour change in the reaction mixture (no gel electrophoresis is required). Additionally the method is highly portable, no specialized equipment is required and a heat block can be used. LAMP is more sensitive than PCR; we have been able to identify < 5 *E. coli* cells without DNA extraction. The method is also highly specific due to the use of 2-3 primer pairs; we are able to target specific stains or pathogen virulence genes. The method can also be combined with fluorescent methods for real-time quantification in the field on battery powered platforms such as the OptiGene II and III. Currently, we are developing assays for the detection of key pathogens including *Aspergillus fumigatus* and *niger*, *E. Coli*, *Legionella pneumophila*, *Bacillus anthracis*, and *Bordetella pertussis*. The method can also easily be adapted to detect specific virulence genes (e.g. *E. Coli* STa) or antimicrobial resistance genes when taxonomic identification alone is not sufficient.

This method is one of a suite of tools we are developing based on high-throughput sequencing and chemical marker analysis which represent the next-generation of methods for in-situ biomonitoring of bioaerosols. We envisage that soon regulators will be able to detect and monitor key pathogens in real time.

7BA.8

Liquid Air Sampler Bias on Bacterial Biodiversity. JOANIE LEMIEUX, Marc Veillette, Nathalie Turgeon, Caroline Duchaine,
CRIUCPQ, Université Laval

Air samplers are essential in bioaerosols study in order to concentrate and analyze the microbial content of the air. In some environments and circumstances, the air can be highly charged with bioaerosols and can contain pathogenic microorganisms such as bacteria, molds and viruses. Bioaerosols can cause diverse illnesses to exposed individuals. Obviously, field sampling is mandatory for exposure assessment studies.

Preliminary data from our laboratory showed a drastic underestimation of biodiversity (microbiota) obtained with a liquid sampler compared to sampling with electrostatic filter (*Veillette & al., American Society for Microbiology General Meeting-Microbe 2017*). A considerable bias may be inherent to the use of different types of air samplers, even when used side-by-side in a single environment. There are two possible hypotheses to explain this divergence in biodiversity obtained: preferential re-aerosolization and preferential sampling.

This study aims at studying preferential re-aerosolization after capture, that is defined by the tendency of a given microorganism to be lost during liquid evaporation occurring while liquid sampling with SKC Biosampler© (SKC Inc.). To study this phenomenon, SKC Biosampler© collection liquid (20 mls) was spiked (n=15) with known concentration of two bacterial strains (*Pseudomonas aeruginosa* and *Staphylococcus aureus*), in known proportions. The fate of the spiked bacterial mix during sampler operation was then followed (before and after 15 minutes, 12.5 L/min sampling). The evaporated liquid (2 mls) content was also captured using a filter (SKC 37 mm closed face cassette, 0.4 µm polycarbonate filter), at the exhaust, between the pump and the sampler. DNA was extracted from SKC Biosampler© liquid samples (*before* and *after*) as well as from the cassette filter and specific qPCRs were performed. *Pseudomonas/Staphylococcus* ratios were then compared throughout the experiment.

When looking at the relative ratios (**RR**) of *Pseudo/Staph* in the *after* samples and in the *before* samples :

[1] $\mathbf{RR}_{\mathbf{P+S,\ a/b}} = (Pseudo_{\mathbf{After}} / Staph_{\mathbf{After}}) / (Pseudo_{\mathbf{Before}} / Staph_{\mathbf{Before}})$

we demonstrated that *Pseudomonas* proportion increases with the use of the sampler (is enriched in the remaining collection liquid) whilst *Staphylococcus* proportion decreases in the remaining liquid.
Consequently, the respective ratios (**R**) of *Staphylococcus* and *Pseudomonas* in the exhaust-connected filter and in the before samples:

[2] $\mathbf{R}_{\mathbf{S,\ f/b}} = Staph_{\mathbf{Filter}} / Staph_{Before}$

and

[3] $\mathbf{R}_{\mathbf{P,\ f/b}} = Pseudo_{\mathbf{Filter}} / Pseudo_{\mathbf{Before}}$

showed that *Staphylococcus* is 4.1 times more enriched in the exhaust-connected filter than in the before liquid (is lost in the remaining collection liquid) when compared to *Pseudomonas* ratio ($\mathbf{R}_{\mathbf{S,\ f/b}} = 0.0118$ and $\mathbf{R}_{\mathbf{P,\ f/b}} = 0.0029$).

Then, when comparing the relative ratios of P*seudo/Staph* in the *after* samples and in the *before* samples[1] ($\mathbf{RR}_{\mathbf{P+S,\ a/b}}$) to the relative ratios of *Pseudo/Staph* in the exhaust-connected filter and in the *before* samples :

[4] $\mathbf{RR}_{\mathbf{P+S\ f/b}} = (Pseudo_{\mathbf{Filter}} / Staph_{\mathbf{Filter}}) / (Pseudo_{\mathbf{Before}} / Staph_{\mathbf{Before}})$

we are able to affirm that *Pseudomonas* is concentrated in the liquid sampler through sampling while *Staphylococcus* as a tendency to be re-aerosolized from the sampler.

Other bacterial strains are being studied to better understand the factors influencing the preferential loss observed. This project showed a different pattern of loss and concentration of two bacterial species, starting to solve the puzzle on the bias involved in liquid air sampling.

7BA.10

Improvement of Cell Extraction from Filters after Bioaerosol Sampling. INKEN SCHULZE-HESSING, Dierk Pöther, Udo Jäckel, *Federal Institute for Occupational Safety and Health*

The impact of bioaerosols on ecosystem dynamics and human health is becoming increasingly evident. Therefore, the microorganism concentration and the community structures of bioaerosols in the environment as well as on work places were intensively studied using different sampling methods. However, studies determining the efficiencies of bioaerosol sampling methods are rare. Thus, the aim of this study was to investigate recovery efficiencies of microorganisms from different filter types commonly used in bioaerosol sampling.

Five different microorganisms were applied on polycarbonate (P) filters as well as on glass (G) and quartz (Q) fiber filters. Following application the bioaerosol sampling was simulated and cells were extracted from filters with a paddle blender. The recovery efficiency was determined a) via total cell counting with the fluorescent DNA stain 4',6-diamidino-2-phenylindole and b) fluorometric quantitation of extracted DNA. Scanning electron microscopy (SEM) was performed to investigate detachment of bacteria from the filter surface.

Significant species-specific differences in recovery efficiencies were revealed. DNA quantitation showed that recovery efficiencies ranged from < 1% to 45%. For *Pseudomonas nitroreducens* applied onto P-filters it was shown that the low recovery rates were mainly the result of insufficient extraction from the filter and attachment of cells to the extraction bags in the paddle blender. SEM pictures revealed bacteria penetrating deeply into the G/Q-fiber filters. However, incubation of exposed G-fiber filters with Proteinase K directly before DNA extraction increased the recovery rates of *P. nitroreducens* cells significantly from < 1% to 69%. Moreover, the incubation with Proteinase K allows the extraction of all tested cells from G-fiber filters without significant species-specific differences in recovery efficiencies.

In conclusion, our study shows the necessity to investigate bioaerosol sampling characteristics to achieve a reliable assessment of bioaerosol exposure. The application of sampling methods with unknown sampling efficiencies may lead to problems in community analyses by concealing the real composition. We were able to show an improved method for cell extraction from filters allowing increased and species-independent recovery.

7BA.11

Development and Optimization of the Electrostatic Precipitator with Superhydrophobic Surface (EPSS) Mark III for Collection of Bioaerosols. TAEWON HAN, Nirmala Thomas, Gediminas Mainelis, *Rutgers, The State University of New Jersey*

In our earlier research, we developed a liquid-based electrostatic precipitator with the superhydrophobic surface (EPSS Mark I and II) for bioaerosol sampling where airborne particles are deposited onto a narrow electrode (3.2 mm) covered by a superhydrophobic substance. The deposited particles are removed and collected by a rolling water droplet (a few tens of microliters) which results in high concentration rates. The Mark I featured a separate charger (commercially available ionizer) and collector, while the Mark II was a single-stage electrostatic precipitator (charger and collector placed in the same chamber). The Mark I and II versions showed high collection efficiency (~70%) for sampling airborne biological particles; however, a commercial ionizer used to charge incoming bioaerosols in Mark I resulted in particles losses as high as 50%, and the ionizer (for the Mark I) and the laboratory made ionizer (for the Mark II) produced high levels of ozone.

Thus, the latest version of EPSS (Mark III) has been entirely redesigned into a two-stage electrostatic sampler (separate charger and collector) for better control of charging process to prevent particle loss in the charger and to minimize damage to collected microorganism due to ozone production during ion generation. Mark III consists of a static air blender, a charger, a transition section, and a collector; it has a shape of a cylinder (1 inch in diameter and ~3 inches in length) and is made of a static dissipative material (Delrin). Also, our earlier developed and low-ozone-producing charger (wire-to-wire design) is integrated with a newly designed collector. This charger features a tungsten wire (0.003 inches in diameter and 1 inch in length) installed in the middle of the charging chamber and connected to high voltage. A ring of stainless steel (SS) wire 0.015 inches in diameter is installed on the inside of the charging chamber at the middle of the tungsten wire and grounded. The collector consists of a grounded SS cylinder (1 inch in diameter) inside the collection chamber and an SS collection rod (6/32 inches in diameter and 2.5 inches in length), which is positioned in the middle of the chamber and connected to a collection voltage. After completing the sampling, the collection rod is removed from the collector and transferred into a glass tube, and then the captured particles are easily extracted using a small volume of water (300-600 microliters) and by ultrasonic agitation for 30 min.

At this stage of development, the Mark III was tested at different collection voltages (-7 to -9 kV), while the charging voltage was fixed at +5.25 kV when challenged with 1 µm in diameter polystyrene (PSL) particles and at flow rates of 10 L/min. The sampler's collection efficiency was determined by measuring the number of particles deposited on the collection rod and the reference filter using mass-balance analysis by a fluorometric method. The collection efficiency was about 55-70% at the flow rate of 10 L/min, and ozone production was below 10 ppb. Further, physical efficiencies were optimized as a function of the collection rod size at different PSL particle sizes (0.5, 1, and 3 µm) and flow rates (10 to 30 L/min). Viability and culturability of cells collected by Mark III were investigated by using ATP bioluminescence, a ratio of Live/Dead cells (flow cytometry), and Colony Forming Units, and compared against that of the reference filter when sampling for 10 min and 8 hours.

7BA.12

Development of Wet-cyclone System for Highly Enriched, Continuous and Automated Bioaerosol Sampling in Real Time. YUSUNG CHO, Seung Chan Hong, Ki Joon Heo, Jae Hee Jung, *Korea Institute of Science and Technology*

According to recent studies, most of the modern people have indoor activities of about 80-90% of the total activity time. As a result, there is a growing interest and demand for increasing social interest in indoor air quality and working environment conditions. Also, it has been reported that the inflow of fresh air from the outside is not performed smoothly due to the airtightness and improper air conditioning system operation, and physiological symptoms such as a headache, drowsiness, dizziness, and concentration decrease are reported. In particular, bioaerosols in fine dust are closely related to various airborne infections such as allergies and respiratory diseases, which can have adverse health effects on humans. Although sampling equipment has been developed for predicting and controlling the risk of fine dust and bioaerosols occurring in various environments, the equipment capable of real-time measurement and analysis has not yet been studied. In this study, we developed a wet-cyclone system capable of liquefying and collecting fine dust and bioaerosol in real time.

The wet-cyclone used in this study used design variables to have high efficiency and low separation particle size of conventional wet-cyclone. Also, the flow ratio (concentration ratio) between injected gas and liquid in the fabricated wet-cyclone was optimized (Orsini et al., 2008). Polystyrene latex spheres (PSL) were sprayed to test the particle collection performance of wet cyclone. Based on the obtained collection performance, the collection performance against bioaerosols was compared with the conventional BioSampler. In addition, for real-time particle collection performance test, the concentration of abruptly changing bioaerosols was compared with UV-APS (Ultraviolet Aerodynamic Particle Sizer), a real-time measurement instrument.

The operating conditions were determined according to the flow ratio between the gas and the liquid injected into the wet cyclone. From this, the particle collection efficiency according to each operating condition was measured. As a result, a collection performance of >99% particle collection efficiency and <1% particle loss was obtained based on 1 µm particles. Also, the wet-cyclone performed in this study showed higher biological collection efficiency than the conventional BioSampler in the evaluation of biological recovery efficiency (*S. epidermidis*). This is because as the gas and liquid are continuously injected into the wet-cyclone, a thin liquid film can be formed on the inner wall of the wet-cyclone, thereby relieving the physical impact when the particles are collected and stably collecting it. Furthermore, the real-time particle collection performance showed that it is possible to sample the concentration that changes every 1 minute after spraying the bacteria (*S. epidermidis*). This shows a similar pattern to UV-APS, which shows excellent performance in collecting and analyzing bioaerosols including fine dust particles in the air, which changes in real-time in various environments.

Our system could be useful for rapid and accurate airborne bioagent detection and monitoring system as an inexpensive, simple, portable, and continuous bioaerosol sampler.

This research was supported by the Ministry of Environment, Republic of Korea (2016000160008) and KIST Institutional Program.

7BA.13

Droplet Microfluidics Based Detector for Bioaerosols. BRIAN DAMIT, *Johns Hopkins University Applied Physics Laboratory*

Robust monitoring technologies for airborne microbes are critical to mitigate the health effects posed by environmental and agricultural bioaerosols, and biowarfare attacks. Limitations of current detectors (e.g. slow response time and expensive consumption of reagents) have compelled the development of new technologies. In this work, a detector was developed which applies droplet microfluidics to bioaerosol detection. Droplet microfluidics, a subfield of microfluidics, is based on the creation of picoliter/nanoliter droplets containing compartmentalized reagents and supports enhanced assays and fluidic manipulations. The bioaerosol detector here functions by precisely focusing aerosols directly into these droplets, and thus harness the benefits offered by a droplet microfluidics platform.

A breadboard detector system was constructed which consisted of an aerodynamic focusing lens, aerosol-focusing nozzle, custom microfluidic droplet chip, and fluorescence microscope. Computational fluid dynamic simulations and Lagrangian particle tracking modeling identified the optimal settings for aerosol focusing into the droplets. Preliminary experiments, wherein test PSL aerosols were focused and deposited onto solid substrates, demonstrated sub 200-µm spot diameters for aerodynamic sizes of 2-5 µm. After obtaining fine aerosol focusing, collection of aerosols in the droplets was achieved by positioning the chip below the focusing nozzle, forming a pinned air-liquid interface at the chip surface, and then focusing test aerosols into that interface. Real-time inspection via microscopy confirmed aerosol capture at the interface. The measured recovery efficiency of aerosols from the droplets was aerosol-size dependent and ranged from about 27% to nearly 100%.

Finally, to prove bioaerosol collection and detection, a droplet propidium iodide (PI) assay was performed: the system distinguished between *E. coli* and non-biological aerosols within 20 s of PI incubation. Overall, this work established the technique of direct collection of aerosols into a convenient droplet microfluidic platform for the purpose of rapid bioaerosol detection.

7BA.14

Continuous Bioaerosol Sampling Using the Super-hydrophilic Silica Coated Wet-cyclone System. YUSUNG CHO, Ki Joon Heo, Byoung Uk Lee, Jae Hee Jung, *Korea Institute of Science and Technology*

Recently, increasing attention has been paid to the relationship between hazardous respirable bioaerosol and human health. Thus, there is growing need to develop the portable bioaerosol detector that can provide the real-time and continuous bioaerosol information. Recently, the bioaerosol analysis techniques based on micro-electromechanical systems (MEMS) have been studied for the miniaturization of the bioaerosol sensor with the accurate and rapid response of target aerosol.

The cyclone system has been used extensively to collect and concentrate airborne particles by the cyclonic action of the fluid in the cylinder. In the 1960's, the development of a wetted-wall cyclone (called wet-cyclone) having nearly continuous liquid flow was started as a means of sampling a large volume flow rate of air (about 1,000 L/min). In recent years, the wet-cyclone system has been developed for the real-time bioaerosol sampler. In this system, the target bioaerosol can be concentrated in a small amount of sampling water. However, the non-uniform and unstable water film condition in the wet-cyclone can yield the significant increase of the particle wall loss. This undesired situation is caused by the unstable momentum balance between air to the liquid stream, the rapid evaporation of the liquid, and the hydrophobic status of the wet-cyclone inner surfaces.

In this study, we applied the super-hydrophilic treatment to the inner wall of wet-cyclone by silica nanoparticle coating to make uniform and stable liquid film. The wettability of the coated surface was evaluated through the water contact angle measurement. Also, the durability test of coatings was conducted from the comparison of the contact angle before and after the sonication process. Finally, the performance of the super-hydrophilic coated wet-cyclone system was evaluated regarding particle collection efficiency and particle wall loss. The collection efficiency was defined as the aerosol to liquid transfer rate. In this test, we used the two types of test aerosol, standard polystyrene-latex particles (PSL) and *S. epidermidis*.

The hydrophilic performance of the polycarbonate surface is gradually increased with silica coating concentration. Additional annealing process of the sample in the dry oven can increase the binding property of the silica nanoparticle film and the substrate; thus its super-hydrophilic property can be maintained despite the 10-minute sonication environment. Finally, the aerosol to liquid transfer rate was increased ~45% to ~99.99% after the super-hydrophilic coating treatment on the inner wall of wet-cyclone.

This research was supported by the Ministry of Environment (2016000160008), the Ministry of Science and ICT (2015R1D1A1A09056879), and KIST Institutional Program, Republic of Korea.

7BA.15

Carbon Stable Isotope Probing Demonstrates Growth of Airborne Methanotrophs. VALDIS KRUMINS, Kevin Dillon, Donna Fennell, *Rutgers, The State University of New Jersey*

Outdoor air holds $10^4 – 10^5$ cells m^{-3}, which until recently have been assumed to be inactive while aloft. We have previously shown that airborne bacteria – outside of water droplets or other aggregates – express proteins and produce ribosomes in response to volatile organic substrates. Here we examine the activity of airborne methanotrophic bacteria using DNA stable isotope probing, and demonstrate that bacteria also are capable of growth (production of DNA) in bulk air.

Methanotrophic cultures were established from rinsate of a maple leaf (dominated by type II methanotrophs) and from an outdoor air sample (containing mostly type I methanotrophs). The cultures were enriched and maintained in minimal media using methane as the sole carbon source. For each reactor run, up to 2 L of liquid culture (fed ^{12}C methane) were concentrated by centrifugation and aerosolized into rotating aerosol bioreactors using a single pass aerosol generator (SPAG, CH Technologies, Westwood, NJ, USA). The 0.32 m^3 paired reactors hold cells aloft for days, and are equipped with on-board sensors for temperature, pressure, relative humidity, CO_2 and methane. After filling with bioaerosols, the reactors were amended with 1500 ppm_v methane. One of the paired reactors received ^{13}C-labeled methane; the other, unlabeled methane. The reactors were rotated at 3 rpm and held at at 22 ^oC for five days. At the end of incubation, ~10^7 cell-sized particles remained airborne. These airborne cells were collected onto 0.8 µm SUPOR membrane filters and immediately frozen (-80 ^oC). DNA extracted from the filters was ultracentrifuged (48,000 x g) for 48 hours on a CsCl gradient. The gradients were then separated into 24 fractions. The particulate methane monooxygenase gene (*pmoA*) and methanotroph-specific 16S rRNA genes (type I or type II methanotrophs, depending on the culture) were quantified in each fraction using real-time polymerase chain reaction (qPCR). In the reactors which received ^{13}C labeled methane, separate DNA peaks representing ^{13}C DNA and ^{12}C DNA were detected in the gradient; while in reactors receiving unlabeled methane, a single ^{12}C DNA peak was detected.

Detection of ^{13}C DNA in the reactors amended with $^{13}CH_4$ is evidence of production of new DNA and thus growth by airborne methanotrophs. The results suggest that microorganisms can metabolize methane, a potent greenhouse gas, while airborne.

7BA.16

Comparative Assessment of Conventional, Fluorometric and Molecular Biomarkers of Airborne Microbial Activity during Condensation Capture and Direct Filtration. MARINA NIETO-CABALLERO, Patricia Keady, Nicole Savage, Mark T. Hernandez, *University of Colorado Boulder*

While the field of aerobiology has experienced rapid growth over the last decade, technology is still lacking that enables engineers and scientists to accurately assess the identity, abundance and activity of airborne microorganisms—both indoors and out. Accurate bioaerosol assessment remains limited by conventional filtration and impaction methods that can compromise, or otherwise influence, the physiologic and metabolic state of airborne microbes, as they are collected from the atmospheric environment.

In response, emerging condensation capture technology was assessed for its ability to preserve bioaerosols in the same physiologic state they exist when suspended in the atmosphere. As judged by direct microscopy, culturing and genetic material content (DNA and RNA), the impacts of whole cell bioaerosol recovery using Condensation Growth Tube Capture ((CGTC), Aerosol Devices, Fort Collins, CO) was juxtaposed to conventional particle filtration. Under this scenario, a full-scale environmental chamber (ca. 11 m^3) was charged with well-characterized pure cultures of bacteria and fungal spores that have often been used to model the behavior of bioaerosols that are relevant to the built environment and environmental health (*Bacillus sp., Mycobacteria sp., Legionella sp.,* and *Aspergillus sp.*). With exception to spores that were dry-aerosolized from a desiccated state, vegetative cells, harvested from liquid culture, were introduced to the chamber air and allowed to age under controlled temperature and humidity conditions. Over several hours, airborne microbes were periodically and concomitantly collected using CGTC and filtration, while being counted, sized and characterized by cytometry using a conventional laser coupled with Ultraviolet Induced Fluorescence ((UVIF), InstaScope, DetectionTek, Boulder, CO).

Bacteria, while in their late exponential growth phase, were aerosolized for ten minutes using a 6-jet Collison nebulizer, reaching an initial concentration at or above 10^5 cells/L in the chamber air. These airborne bacteria were collected by CGTC directly in the following liquids that were continuously chilled to 4^oC: phosphate buffered saline and a genetic preservative (DNA/RNA Shield, ZymoBIOMICS, Irvine, CA). Cellular preparation (washing) and extended nebulization time had no effect on culturability, cell size or cell count.

A time-series of recovery experiments was performed at different humidity levels (30% and 80%). Samples were aseptically taken from CGTC wells for 10 minutes after 30, 60, 90, 120, 150 and 180 minutes of aerosol aging in the chamber, following the initial aerosolization. This provided a means to independently isolate and compare cellular deposition rates as judged by the different recovery methods. Direct microscopic and cytometric counts were in agreement with the time-series recovery of airborne DNA gene copy numbers, obtained using quantitative PCR (qPCR) with universal bacterial primers. Quantitative PCR steadily recovered between 3 and 4 fold higher gene copy numbers than its direct microscopic counterpart, consistent with whole cell microorganisms containing multiple copies of the target 16s rDNA gene. As anticipated, a significantly lower and age-dependent response was observed from the standard culturing of colony forming units (CFUs) on rich, broad spectrum agar (R2A). About 0.1% of the microorganisms aerosolized could be recovered as CFUs; however, culturable cells rapidly declined below detection (<60 min) while the optical methods indicated orders of magnitude higher airborne cell numbers, consistent with amplicons of (phylo)genetic DNA and RNA targets. The direct recovery of whole cells into genomic preservative, suggests the persistence of different RNA pools that can be used as a robust activity indicator in this time window. Moreover, the optical diameter of the airborne bacteria collected significantly diminished during aerosol aging as judged by aerosol cytometry and direct microscopy.

7BA.17

Development of an Immunoassay for Detection of the Nitrated Form of Allergenic Ragweed Protein (nAmb a 1).

COURTNEY SEFFENSE, J. Alex Huffman, *University of Denver, CO*

The frequency of allergic conditions has risen over the past several decades, particularly in urban areas. It has been hypothesized that one cause for this rise may be links between allergenic pollen and urban pollutants. For example, secondary pollutant gases ozone and nitrogen oxides have been shown to react with tyrosine residues within certain proteins and that these chemically modified proteins can increase their allergenicity.

Thus far, relatively little investigation has been directed toward the measurement of nitrated proteins in ambient aerosol, and so the hypothesis about the urban pollen allergy phenomenon has not been well tested. One reason for the lack of measurements is the high relative cost and complexity of techniques to detect and quantify nitrated allergens in atmospheric samples. Several papers approximately 15 years ago pioneered the investigation of nitrated proteins in ambient samples [1,2], but since that point little study has been focused on ambient field samples. Laboratory work over the last decade has focused on aspects of the chemistry of protein nitration and oligomerization, using the birch pollen protein Bet v 1 as a model [i.e. 3-5] and other related work has utilized the human protein lactoferrin as a model [6].

Franze et al. [1,2] utilized an enzyme-linked immunosorbent assay (ELISA) technique to detect and quantify nitrated protein material in ambient aerosol samples. Following this initial work, we have begun to develop a sandwich ELISA protocol for the selected detection of nitrated Amb a 1 (nAmb), which is a key allergenic protein in Ragweed pollen, a ubiquitous allergen in many areas of the United States and Europe. The assay entails sandwiching the protein to be detected (antigen) between two antibodies and detecting the change in color, which varies a function of the antigen concentration. Our initial work has focused on nitrated bovine serum albumin (nBSA) protein as an inexpensive antigen model as we optimize procedures. We have recently begun optimizing a parallel procedure to detect nitrated nAmb, toward the eventual goal of applying the assay to samples of airborne pollen collected in the field. We will discuss details of the ELISA protocols, discussing factors affecting reliability of assay calibration curves. Initial work testing both the nBSA and nAmb protocols shows encouraging results.

The work is being conducted as a part of an undergraduate research thesis by Courtney Seffense and is supported, in part, by the University of Denver Undergraduate Research Center (URC).

Effects of Temperature and Water Condensation on the Sampling of Infectious Influenza H1N1 Virus Aerosol through Water-based Condensational Growth. MAOHUA PAN, Leah Carol, Aneal Mamane, John Lednicky, Arantzazu Eiguren Fernandez, Susanne Hering, Hugh Fan, Chang Yu Wu, *University of Florida*

Inhalation exposure to airborne influenza viruses can pose major health risks to humans and animals, and potentially result in significant economic losses. A 2017 study reported that up to 646,000 people in the word die every year of influenza. However, studies about sampling of airborne infectious influenza viruses are limited due to inefficiency of existing virus aerosol samplers, and the sampling conditions vary a lot considerably, making sampling results difficult to compare to each other. In prior studies, we demonstrated high collection efficiency for airborne infectious influenza H1N1 viruses by the VIable Virus Aerosol Sampler (VIVAS). The objective of this study was to evaluate the effects of temperature and amount of water condensed onto the collection liquid of SESI (Super-Efficient Sampler for Infectious virus, an improved version of the VIVAS) on the viability of the collected infectious influenza H1N1 viruses.

In controlled laboratory experiments, H1N1 influenza virus (80-120 nm) was aerosolized using a Bioaerosol Nebulizing Generator (BANG) and the aerosolized virus was collected by the SESI. This SESI is composed of four components: Conditioner, Initiator, Moderator, and Collector. Sampling temperatures (10, 20, and 33ºC) were pre-set for the Collector, whereas the moderator's temperature was adjusted accordingly to keep the accumulated collection liquid to minimum (< 0.1ml). During tests of the effects of volume of accumulated condensed water on virus viability, the temperature of the collector was kept at 10 ºC whereas the Moderator's temperature was changed from 6 to 14 ºC, which resulted in different amounts of accumulated water in the collection media. PBS with 0.5% w/v BSA Fraction V was used as the collection liquid, and Madin Darby canine kidney (MDCK) cells using a standard median tissue culture infectious dose (TCID50) assay was used to determine the infectious virus titer (#/mL) of Influenza H1N1 virus.

When the sampling period was 20 min, survivability of the influenza virus was higher when the collector temperature was 10 ˚C or 33 ˚C than at 20 ˚C. Further analysis is needed to explain this reproducible finding. The amount of water condensed onto the collection liquid during the 20 min sampling did not have significant effects on the viability of the infectious viruses, which suggest that this parameter need not to be taken into consideration for sampling infectious influenza viruses within 20 min. This is the first time the effects of sampling temperature and the amount of water condensed onto the collection liquid on the viability of infectious viruses are evaluated using a SESI.

Efficiency of a Biotrickling Filter to Reduce Bioaerosol Emissions from Pig Buildings. JONATHAN M. VYSKOCIL, Valérie Létourneau, Matthieu Girard, Ariane Lévesque, Caroline Duchaine, *Université Laval*

Pig pathogens are released into the air by the exhaust fans of livestock buildings and may consequently contaminate nearby barns. The development of strategies to reduce bioaerosol emissions is then required as preventive measures. Outgoing air filtration systems can be used to reduce the risk of spreading infectious diseases to other farms during viral or bacterial outbreaks. The present study aims to characterize the effectiveness of a biotrickling filter, an air treatment unit (ATU), developed by the Research and Development Institute for the Agri-Environment (IRDA) to reduce the bacteria and viruses emitted from a pig building. The biotrickling filter consists of an inert filter media which supports a microbial community continuously fed through a nutrient solution sprayed over incoming air. Bioaerosols were sampled isokinetically and simultaneously upstream and downstream of two biotrickling filters (field replicates) using two high volume air samplers (Coriolisμ Biological Air Sampler, Bertin Corp.). Data recorded during each sampling include the temperature of air before and after the ATUs, the air flow rate within the ATUs, and the relative humidity of air entering the ATUs. The samples were collected in the summer, fall, and winter. A culture-based approach and molecular biology analyses were used to monitor microbial concentrations and populations captured and emitted by the biotrickling filter. Preliminary results show an increase in culturable bacteria downstream of the ATUs, but a decrease in total bacteria (qPCR). *Clostridium perfringens*, *Enterococcus*, and *Escherichia coli* were quantified by qPCR. While *C. perfringens* and *Enterococcus* concentrations were below the limit of quantification, *E. coli* were detected in samples. Any factor associations with *E. coli* concentrations before and after the ATUs are yet to be resolved. Illumina MiSeq Next Generation Sequencing Biodiversity Analyzes will be used to determine if the biofilter bacteria are being released and examine pig pathogens that are being removed by the biotrickling filter. Quantification of archaea and porcine circovirus by qPCR will as well be conducted in the next months. Strategies to eliminate air contamination between pig buildings need to be developed and used in the field as air spreading of pig pathogens is possible and as biosecurity measures already in place are inefficient to eliminate the overall contamination risk.

7BA.22

A Further Investigation of Non-thermal Plasma Inactivation of Airborne Viruses Using a Newly Designed Coaxial Plasma Discharge. TIAN XIA, My Yang, Ian Marabella, Abby Kleinheksel, Eric Monsu Lee, Bernard Olson, Darrick Zarling, Montserrat Torremorell, Herek Clack, *University of Michigan*

Porcine Reproductive and Respiratory Syndrome (PRRS) is one of the greatest threats to modern pork industry. The virus has been detected in air more than 9 km downwind of infected swine. Applying HEPA filtration, the traditional bioaerosol control technology, to ventilation air supplied to hog barns involves structural retrofits to buildings that can be costly, in addition to the periodic replacement of used filters. Non-thermal plasmas (NTPs) are electrical discharges comprised of reactive radicals and excited species that inactivate viruses and bacteria with minimal pressure drop. Our previous experiments using a packed bed non-thermal plasma reactor demonstrated effective inactivation of bacteriophage MS2 as a function of applied voltage and power. The present study examined the effectiveness of the same reactor in inactivating aerosolized PRRSv and the effectiveness of a newly designed coaxial plasma discharge reactor in inactivating aerosolized MS2. A PRRSv solution containing ~105 TCID50/ml was aerosolized at a rate of 3 ml/min by an air-jet nebulizer and introduced into air flows of 5 or 12 cfm followed by NTP exposure in the reactor. Two impingers sampled the virus-loaded air flow at both upstream and downstream positions of the reactor. Subsequent TCID50 assay and quantitative polymerase chain reaction (qPCR) analyses of the collected samples determined the pre- and post-treatment abundance of infective PRRSv (in TCID50/ml) as compared with the abundance of the viral genome (qPCR), whether infective or rendered inactive by NTP exposure. An optical particle sizer measured upstream and downstream aerosol size distributions, giving estimates of aerosol filtration by the reactor. The results showed that PRRSv was inactivated to a similar degree as MS2 at the same conditions, with the 1.3-log inactivation of PRRSv achieved at 20 kV and 12 cfm air flow rate. Differential pressure across the reactor was minimal compared to HEPA filters and a consumer-grade ozone filter reduced residual ozone concentrations down to levels commensurate with the ambient laboratory environment. The results demonstrate the potential of properly optimized NTPs for preventing infiltration of PRRSv into hog barns with ventilation air. Having established MS2 as a conservative surrogate for PRRSv, the present study also examines the MS2 inactivation efficiency of a new annular non-thermal plasma reactor design equipped to vary the gap distance between the electrodes. The coaxial electrode configuration is expected to generate a more evenly distributed plasma discharge and be easier to model in future studies.

7BA.24

Investigation of Oxidation Effect in Inactivation by an Electrostatic Precipitator with Humidifier. TAKUMI YAZAWA, Munehiro Shiraisi, Akinori Zukeran, Risei Wada, Jun Sawai, *Kanagawa Institute of Technology*

An electrostatic precipitator (ESP) can eliminate and inactivate airborne microorganisms to improve indoor air quality. Therefore, the authors have investigated to inactivate microorganisms collected on a collection electrode in a two-stage type ESP. As a result, the inactivation effect was significantly improved by humidification 1).

In this study, experiments were carried out to investigate the process of improving the inactivation effect. The concentrations of ozone in the gas and the reactive oxygen speacies (ROS) reached the surface of collection electrodes were measured, and the oxidation effect of ROS on the collection electede was evaluated using a decolorization test paper dyed with indigo carmine.

The experimental ESP has a two-stage structure of a discharge section and an electrostatic section. The discharging section has a wire-and-plates configuration composed of a high-voltage application wire electrode and grounded plate electrodes. The electrostatic section has a parallel-plate electrode structure composed of a high-voltage application electrode and grounded plate electrodes. The discharging section was supplied with DC voltage of between -8.5 kV and -9.5 kV to generate corona discharge, whereby the discharge current was adjusted to 19 µA, which maintained the ozone concentration of approximately 1 ppm. The electrostatic section was supplied with DC voltage of - 5 kV to form an electrostatic field. The gas velocity was adjusted to 0.5 m/s, and the relative humidity (RH) was controlled between 5 % and 95 % using a hulnidifier. The ozone concentration was weasured using an ozone monitor at the downstream side of the ESP. In order to observe the distribution of ROS reached the surface of the grounded plate electrodes, the gel reagents reacted with ROS were located on the electrodes. The oxidation effect of ROS reached the electrode surface was estimated using decolorization test paper dyed with indigo carmine which was located on the plate electrode.

As a result, the ozone concentrations at the case with and without the humidifier were approximately 0.9 and 1.1 ppm, respectively. The concentration decreased by using the humidifier.

ROS distribution on the grounded plate electrode had a maximum value at the location under the wire electrode in the discharge section, and that decreased on the downstream side in the electrostatic section. The distribution in the case without humidifier was almost the same with that with humidifier. Thus,the ROS distribution were not influenced by RH.

However, the test paper dyed with indigo carmine in the case with the humidifier was decolorized on the downstream side from the wire electrode due to oxidation effect of ROS, althoug that in the case without the humidifier was not decolorized.

These results indicate that the improvement of inactivation effect with the humidifier would originate from that moisture or water droplets absorbing ROS such as ozone attached and be held on the electrode surface.

Performance of Silver, Zinc and Iron Nanoparticles Doped Cotton Filters against Airborne E. coli to Minimize Bio-aerosol Exposure. Attarad Ali, Maohua Pan, TREVOR TILLY, Muhammad Zia, Chang Yu Wu, *Quaid-i-Azam University Pakistan, UF Gainesville USA*

Various designs of air-cleaning devices and filters are available to trap and deactivate aerosolized microorganisms that cause human diseases; however, there are limitations to these methods that still need to be resolved, including elevated pressure drop, decreased flow rate, short life-span, regenerative capacity, as well as fouling and clogging due to microbial proliferation. The objective of this study was to evaluate novel nanoparticle (AgCt, ZnCt, FeCt) doped cotton filters, developed in our previous studies, as biocidal filters for bioaerosol attenuation. To evaluate the biocidal activity of the nanoparticle impregnated filters, lab-generated E. coli aerosols were nebulized and were drawn through the filters and a BioSampler for comparison. The dryness of the aerosol affected the survival of bacteria collected on the filter. The relative humidity (RH) of the aerosol was varied from 20% to 90% using the control (cotton) filter, and the optimal RH for collecting maximum viable counts (colony forming units, CFUs) was found to be 50±5%. The permeability for untreated cotton filter was measured to be 3.38×10-11 m2 while that for the silver doped filter (AgCt) was slightly higher at 3.64×10-11 m2; meanwhile, the FeCt and ZnCt filters demonstrated comparatively lower permeability at 2.06×10-11 m2 and 1.86×10-11 m2, respectively. Overall, the permeability values of these filters were within the range commonly found for filter media used in industrial bag filters. The doped filters showed initial viable removal efficiency (VRE; 1 – downstream concentration/upstream concentration collected by the BioSampler) as 100% whereas the control filter was only 80.09±3.13%. Afterward, the nanocomposite doped filters retained their viable efficiency (~99%) for four filter cycles where they were used to collect E. coli, rinsed and oven dried, while the control filter demonstrated VRE of 76.6±3.2%. Among the three filters, the AgCt illustrated the maximum VRE (99.5±0.23). The relative survival fraction (RSF) was determined by comparing the viable counts of collected microbes from an untreated cotton filter and a doped filter. The maximum RSF of 0.033±0.006 was exhibited by FeCt followed by ZnCt and AgCt (0.015±0.005 and 0.0063±0.0005, respectively). The pressure drop of AgCt was also notably found low as compared to other two filters (ZnCt and FeCt) and even control as well. The physical removal efficiency (PRE) determined by an Optical Particle Counter was 99.9±0.7% for ZnCt, 97.4±1.2% for AgCt and 97.3±0.6% for FeCt, where the control (cotton) showed only 77.4±6.3% for particles >500 nm. Overall, these results suggest that nanocomposite doped filter media, particularly AgCt, can provide effective protection against airborne pathogens with a lower pressure drop, elevated collection efficiency, and better disinfection capability as compared to untreated cotton filters, which are all important features for practical biocidal applications. The metal ions released in extraction liquid (PBS) after each cycle of filter reuse were analyzed by inductively coupled plasma optical emission spectroscopy (ICP-OES) and will be reported in conference.

Development of a Novel Biomimetic Platform for Simulating Human Respiratory Infections. David Drewry, Brian Damit, FELIX SAGE, Julia Patrone, *Johns Hopkins University Applied Physics Laboratory*

Airborne respiratory infections (e.g. inhalation of viruses, bacteria, or fungi) pose a serious threat to global health and current methods for studying human physiological response fall short for agents untestable on humans. Current methods used to study airborne transmission consist of aerosol deposition directly onto in-vitro cell cultures or exposure to in-vivo and ex-vivo animal models. Although used extensively, animal models are expensive and experimental results are challenging to extrapolate a human response due to anatomical and physiological differences. In-vitro models lack a realistic delivery method for bioaerosols and the benefit of multicellular and whole organisms response. This research seeks to address these shortcomings through the development of an experimental platform that provides a more realistic insight into pathogenesis and delivery of aerosol particles to human cells. The platform consists of an additive manufactured, anatomically-realistic upper respiratory tract for an average human male. The airway includes the mouth, trachea, and bronchi (to the third bifurcation) coupled with “inserts” seeded with human A549 cells. Embedded at various locations in the cast, these inserts match the natural curvature of the respiratory tract and allow for bioaerosols drawn into the platform to deposit naturally on the cells. Initially, inserts without A549 cells were subjected to bioaerosol loading to examine aerosol deposition location and to establish dose during an aerosol challenge. Airflow through the cast was representative of inhalation during light exercise. Finally, inserts were seeded with viable A549 cells and exposed to a model bacterial agent (*Staphylococcus epidermidis*). Infectivity was evaluated through live-dead staining and fluorescent microscopy. This type of platform is an important innovation in modeling whole-organ systems that can be paired with recent advances in bio-printing on the path to creating organotypic test beds. This will allow researchers to perform experiments that are more cost-effective, and that more faithfully represent airborne infection in humans.

Chemical Characterization of Combustion Aerosols Related to Wood Combustion and Internal Combustion Engines.

THORSTEN STREIBEL, Hendryk Czech, Jürgen Orasche, Toni Miersch, Martin Sklorz, Johannes Passig, Olli Sippula, Jorma Jokiniemi, Benjamin Stengel, Bert Buchholz, Ralf Zimmermann, *University of Rostock and Helmholtz Zentrum Munich, Germany*

Combustion related aerosol emissions exhibit a considerable impact on human health and the climate. They contribute to a large extent to the formation of ambient aerosol, which is known to cause adverse health effects. Although the association between ambient aerosols and adverse health effects is very well established by epidemiology, it is still not well understood which aerosol fractions or properties are responsible for the observed effects.

For a better understanding of these interrelations, a thorough chemical characterization of the emitted aerosol from various combustion sources is of high importance. In the framework of the Virtual Helmholtz Institute HICE, several measurement campaigns have been carried out devoted to a comprehensive analysis of gas phase products and particles produced by different combustion sources. Utilized measurement techniques comprised on-line methods based on photo-ionization mass spectrometry for real time analysis of gas phase components, and filter sampling for particulate matter followed by chemical analysis using gas chromatography/mass spectrometry. A second analytical method for chemical characterization of particles consisted in a hyphenation between a thermal/optical carbon analyzer and a photo-ionization time-of-flight mass spectrometer.

For example, the consumption of fuel wood as a renewable energy source is rising in developing and industrialized countries because of environmental, economic and political aspects. Aerosol emissions of state-of-the-art wood combustion compliances, namely a logwood operated masonry heater with air-staged secondary air supply and a pellet boiler have been investigated. For the masonry heater, spruce and pine wood served as fuel. Pine wood emitted significantly higher amounts of organic compounds than spruce wood. The pellet boiler showed considerable lower emission factors with respect to organic substances. An interesting aspect was the observation from simultaneous exposure experiments with lung cell cultures, that compared to diesel exhaust wood combustion aerosol exhibited less severe biological responses on transcriptome and proteome level, although it emitted higher concentrations of aromatic species.

Aging of the emitted aerosol was realized by a flow-tube reactor to investigate the potential of wood combustion aerosol for the formation of Secondary Organic Aerosol.

A second combustion source consisted of a gasoline engine test bench. The engine was run with gasoline containing 10 % of ethanol and with E85, a mixture of 85 % ethanol and 15 % gasoline. Two driving cycles were applied, one reflecting urban traffic, the other driving with high velocities between 80 and 180 km/h for four hours. E85 showed much lower emission of particles and aromatic species, but high gas phase emissions of unconsummated ethanol and acetaldehyde. Driving with high velocities using E10 fuel led to a perceptible increase of polyaromatic hydrocarbons and carbon monoxide emissions.

7CB.3

Water Sorption Phenomenon on Aerosols Emitted during a Fire: Determination of the influencing Physico-Chemical Parameters.

LAURA LINTIS, Alexis Coppalle, François-Xavier Ouf, Cécile Vallières, *Université de Lorraine/IRSN*

Fire constitutes a hazard in a nuclear facility. It can lead to the clogging of HEPA (High Efficiency Particulate Air) filters by soots which are aggregates of carbonaceous primary nanoparticles. The presence of water leads to a higher filter airflow resistance. The water condensation on particles, initiated by an adsorption process, must be taken into account in order to better estimate the clogging process. This study consists in determining the most influencing physico-chemical parameters of soots on the adsorption phenomenon.

Combustion of isolated fuels heptane, PMMA and hydraulic oil has been carried out at analytical scale in a controlled atmosphere calorimeter cone. Fire tests were performed at two dioxygen concentrations: 21% and limit dioxygen concentrations before extinction in order to mimic the vitiated surrounding atmosphere occurring during a fire in a confined local. Online analysis including a SMPS (Scanning Mobility Particle Sizer) and ex situ physico-chemical analysis were carried out to determine the morphology, densities, specific surfaces and chemical surface compositions.

The CMD (Count Median Diameter) measured at 21% of dioxygen concentration presents values between 160 and 200 nm. A CMD diminution of 10% up to 50% depending on the fuel was observed for the minimal dioxygen concentrations. This aggregates CMD obviously influenced by dioxygen concentration is a parameter controlling the soot cake porosity during clogging processes. Transmission electronic microscopy pictures analysis lead to values of primary particles diameters of 30 and 36 nm for heptane and PMMA soots respectively. Unlike the aggregates CMD, these primary particle diameters do not change significantly with the dioxygen concentration. The elemental analysis leads to almost identical carbon amounts of about 90% at 21% of dioxygen concentration and show a diminution of 2% at the minimal dioxygen concentration. Organic carbon amounts are systematically higher for soots produced in a vitiated atmosphere. Heptane shows the most significant increase from 1% to 18%.

Water uptake has been measured at a constant temperature of 25°C for different relative humidity using a Dynamic Vapour Sorption Vacuum microbalance. As a preliminary step, water sorption measurements have been performed for two reference black carbons with primary particle diameters of 25 and 95 nm. Water uptakes of 10% for the lowest diameter and 1% for the highest highlighted a clear influence of this primary particle diameter on water adsorption. Identical water adsorption isotherms were obtained for samples compacted in pellet of 60% apparent porosity and left at looser powder state characterized by porosities close to 98%. It excluded the apparent porosity and indirectly the CMD as influencing parameters on sorption process. Soots present similar water uptakes of 3% at 90% of relative humidity. The isotherm shapes are characteristic of Vth type isotherm (*Rouquerol et al.*, 2014), reflecting a multilayer adsorption mechanism on hydrophobic adsorbents. However, water uptakes obtained at minimal dioxygen concentrations are systematically 0,5% higher than those obtained at ambient concentration. Those discrepancies can be explained by higher organic carbon amounts and lower carbon element amounts with the dioxygen concentration decrease previously indicated. The primary particle diameter was brought out as major influencing parameter on water sorption phenomenon occurring on soots.

For comparison, water isotherms of IIth type were obtained with realistic fire soots. They were collected on a HEPA filter during a large scale fire of a gloves box essentially composed of PMMA walls. The concave shape at low humidities is characteristic of high interactions with water. The water uptake increase up to 6% at a relative humidity of 90% reveals the beginning of the capillary condensation stage. Realistic soots have been found having a hydrophilic behavior compared to the soots produced at analytical scale.

7CB.4

Real World Emission Factors of Fine Aerosol and Carbonaceous Constituents from On-Road Transport in India. JAI PRAKASH, Dilip Ganguly, Gazala Habib, *Indian Institute of Technology Delhi*

Accurately measuring emission factors (EFs) are prerequisite for the correct emission estimates. The radiative forcing of carbonaceous constituents of aerosol (Elemental and Organic Carbon) are agreed to have significant climate implications over South Asia including India and China, where the abundance is high. However, a large discrepancy between model simulated and satellite retrieved absorbing aerosol optical depth was estimated in recent work by Bond et al (2013). The lack of knowledge on regional source activity, technological advances and unavailability of emission profiles of regionally important sources are stated as main reasons for such incongruity. For Indian on-road transport sector the emission estimates relied on EFs of PM2.5 measured either using chassis dynamometer following standard driving cycle or derived from emission models, and fraction of EC and OC adopted from literature for other countries. These EFs introduced an undefined uncertainty in recent emission inventories of road transport sector. None of the study has reported EC and OC emission factors for Indian vehicles. Therefore, for the first time, a technology based emission factors of OC and EC measured during on-road operation of vehicles in Delhi were used for refining the emissions estimates for the base year 2013. A logistic model was used with fixed parameters and vehicle registration data for the year 2013 to estimate the on-road vehicle population. The on-road vehicles were dominated by 2Ws, followed by 4Ws, others, LMVs-goods, HDVs-truck and buses with new vehicles comprising the majority of the on-road fleet. A portion of superemitter, which is highly unreliable, was assumed as 17% of the on-road population. Vehicle mileage and annual distance traveled were compiled from the literature and thus, fuel consumption was estimated at national level and disaggregated state to district level using vehicle population as proxy. Emissions of PM2.5, EC and OC were estimated as 260 (134-386) Gg y-1, 123 (65-181) Ggy-1 and 84 (37-130) Ggy-1 respectively. The PM2.5, EC, and OC emissions from the on-road transport sector for the base year 2013 contributed 7%, 17%, and 6% of total emissions from India. Another important finding of this work is new vehicles emit 70-80% of national level PM2.5 and EC compared to old vehicles, while old and new vehicle both equally contributed to OC emissions. The new emission factors from on-road measurement and emission estimates for on-road transport sector and its implications in climate forcing will be discussed.

7CB.5

Chemical Characterization of Biomass Burning Sources Using Targeted and Untargeted Approaches. CAMILLE NOBLET, François Lestremau, Jean-Luc Besombes, Olivier Favez, Serge Collet, Alexandre Albinet, *INERIS*

Biomass burning is a significant source of particulate matter (PM) in ambient air. To date, the evaluation of the distinct contributions of both, wood burning, used for residential heating, and green waste burning, on PM concentration levels is difficult and rarely achieved. Such discrimination is of major concern for air quality policy-makers in order to implement effective actions to reduce air pollution. The main objective of the research project SODEMASS (bioMASS burning SOurces DEconvolution) is to identify specific organic molecular markers and/or chemical patterns of both biomass burning sources that can be further used in PM source apportionment studies. Several experiments have been performed in “real” conditions using different wood combustion appliances such as a residential wood stove and a fireplace. Several parameters have been investigated including the output conditions (nominal vs reduced) and the wood log moisture content (mix of species including beech, oak, and hornbeam). In addition, green waste burning experiments have been carried out in a large combustion chamber facility (1000 m^3) using two kinds of burning material such as grass mowing with tree leaves and hedge trimming with branches. Several physicochemical parameters (smoke temperature, O_2, NO_x, CO, CO_2, non-volatile PM concentrations) were monitored continuously by using automatic sensors or analyzers and about 50 PM samples (on quartz fiber filters) have been collected after dilution of the channeled smoke (dilution factor about 1000). Filter samples have been characterized using both, targeted (levoglucosan and its isomers, methoxyphenols, alkanes, polyols, catechols and derivatives as well as EC/OC) and non-targeted (high resolution mass spectrometry (Q-TOF) coupled to GC or LC) approaches. The data treatment and statistical analysis will allow highlighting specific organic molecular species (exact mass, retention time, molecular formula, MS/MS fragmentation…) or chemical pattern candidates of each biomass burning source.

7CB.6

Waste Burning Tracers in Residential Wood Combustion Area in Estonia. HANNA LII KUPRI, Marek Maasikmets, Riin Rebane, Erik Teinemaa, Viktoria Voronova, *Estonian Environmental Research Centre*

Estonia's health impact assessment study has shown that due to the fine PM in an ambient air, people's life expectancy has shortened up to 13 months, with the highest decrease in city centers or areas with extensive domestic heating (Orru, 2011). During domestic heating, often incomplete combustion occurs causing the formation of polycyclic aromatic hydrocarbons (PAH).

One of the biggest fraction in Estonia's municipal solid waste (MSW) consists of different plastic materials. Major compound in the smoke from burning plastics include terephthalic acid (TA), used predominantly in beverage bottles and similar containers (polyethylene terephthalate - PETE), polystyrene (PS), polyporopylene (PP), etc. The specific key organic tracer for burning plastics found in atmospheric particle samples also include 1,3,5-triphenylbenzene, which occurs in regions where plastic waste is burned (Simoneit, 2005). This suggests that combustion of waste which is largely composite of plastic materials can be traced using the characteristic species detected in the smoke of plastics and refuse burnings (Kumar, 2015). Currently, there are only few available studies related to tracers for plastic waste burning in aerosols.

As Estonia has a well-organized MSW systems, it can be assumed, that people are not burning waste to dispose of it, but it could be considered more as an habitual behavior. According to the members of Estonia's Chamber of Chimney Sweepers, in addition to the wood, paper and cardboard waste, people also tend to burn Tetra Pak®'s, sanitary napkins, diapers, various plastic packages, shoes, textile etc. According to the Estonian Environmental Inspectorate, it is difficult to assess the exact number of people who still practice burning household waste since such activities are done clandestinely. Burning waste can also be an important contributor to particle pollution, because wood and wood chips account more than 90% of the fuel used for Estonia's residential heating. Therefore, it is an important topic to address.

Methods and results

The analysis of aerosol chemical composition (using Aerodyne Aerosol Chemical Speciation Monitor) were carried out during the winter period of 2016 and the full year of 2017 in Tartu's residential wood combustion (RWC) area and Lahemaa EMEP background monitoring station. PM10 and PM2.5 levels in ambient air were measured using beta ray attenuation (BAM 1020, MetOne) analyzers and for PM10 gravimetric measurements high-volume sampler (Digitel DHA-80) was used.

For analyzing terephthalic acid 24 h high-volume filters were extracted by sonication-assisted solvent extraction and then analyzed with liquid chromatography tandem mass spectrometry (LC-MS/MS). Chromatography was performed on a reversed phase column with methanol and 0.1% formic acid as chromatographic eluents. Gas chromatography mass spectrometry (GC-MS/MS) was used for analyzing heavy metals and PAH's. Heavy metals (Al, As, Sb, Cd, Co, Cr, Mn, Mo, Ni, Pb, Se, V, Fe, Zn, Cu) were analyzed on ICP-MS (Agilent series 7500).

Contrary to widespread bias, MSW combustion is not only a problem in developing countries, but it is also taking place in Europe. In this research, we have found that the packaging waste combustion in household heaters and stoves might be quite an important issue in some RWC areas. The analysis has shown a good correlation of TA, PAH and benzo(a)pyrene which may have been released to the environment during incomplete co-combustion of wood and waste materials. Analysis of filters from both stations also showed increased amount of TA and benzo(a)pyrene during the heating period and during summer when people make bonfires.

Toxicological and Chemical Characteristics of Fine Particles from Burning of Crop Residues in China. KIN-FAI HO, Jian Sun, Haiyan Ni, Jie Tian, Yongming Han, Junji Cao, Hsiao-Chi Chuang, *The Chinese University of Hong Kong*

Crop residue burning is a major source of fine particulate matter and arouses significant concern in China and worldwide due to its adverse impacts on environment and human health. Five types of crop residue (rice straw, wheat straw, corn straw, sugarcane straw and sorghum straw) were selected and burned in a laboratory combustion chamber to mimic the combustion process. Total 28 sets of $PM_{2.5}$ samples were collected to determine their chemical and toxicological characteristics. Human lung alveolar epithelial A549 cells were exposed to $PM_{2.5}$ at concentrations of 0, 20, and 150 µg/ml for 24 hours. The cell viability and toxicity were measured by the trypan blue dye exclusion assay and lactate dehydrogenase (LDH) / interleukin 6 (IL- 6) release, respectively. Burning of wheat straw emitted the highest level of $PM_{2.5}$ while sugarcane and sorghum straw emitted the lowest. Carbonaceous species, organic carbon (OC) and elemental carbon (EC), were the dominant components in all samples which contributed ~50% of $PM_{2.5}$ in total. The ratios of OC/EC from crop residue burning ranged from 8.8 to 31.0 which were significantly higher than those emitted from wood and fossil fuel burning. Potassium (K^+) and chloride (Cl^-) are dominant water-soluble ions from crop residues burning, with an average abundance of 6.4 ± 4.4% and 14.5 ± 8.2% in $PM_{2.5}$, respectively. Exposure to $PM_{2.5}$ at the concentration of 20 µg/ml to 150 µg/ml decreased cell viability and increased LDH / IL-6 release. Strong negative correlations were found between cell viability and OC ($R = -0.66$) and some heavy metals such as Cr, Mn, Fe, and Ba ($R < 0.65$). Moreover, OC, Cr, Mn, Fe and Ba also showed strong positive correlations with LDH and IL-6 responses. However, $PM_{2.5}$ samples emitted from burning of sorghum straw showed the lowest levels of LDH and IL-6 (150 µg/ml exposure) which may be due to the lower abundance of OC and heavy metals in $PM_{2.5}$. In conclusion, our data indicate that $PM_{2.5}$ emitted from biomass burning contained high concentrations of OC and toxic metals which were strongly correlated to cell viability and inflammatory responses. The findings suggest a need to control the burning of crop residues which can induce significant health impact on human being.

7CB.8

Particulate Emissions from Residential Biomass Hydronic Heaters. Patricia Fritz, Brian P. Frank, NICOLE VITILLO, Marilyn Wurth, Jake Lindberg, Shida Tang, Dave Guerrieri, Thomas Wainman, Gil H. LaDuke, Todd Crawford, Nathan Walz, *New York State Dept. of Health*

Currently, residential wood combustion units are certified for particulate emissions on the basis of mass emitted. Mass-based standards essentially ignore particle emissions in the ultrafine size range that contribute significantly to the number of particles emitted but make negligible contribution to particulate mass. To inform energy policy, and to identify potential mitigation strategies beyond reductions in PM mass, direct measurements of the particulate number concentration and size distribution of PM emitted from residential wood combustion units are needed.

We conducted a laboratory study of residential wood combustion devices in collaboration with an emissions testing group. Particle concentrations were measured over the size range of 10nm to 10um with a suite of instruments capable of providing fine time scale resolution (e.g., one second) to capture rapid changes in the exhaust particulates with changing operational loads. We selected instruments employing a variety of particle measurement technologies, including an aerodynamic particle instrument (Dekati, ELPI+), an electrodynamic particle sizer and counter (TSI Nanoscan SMPS), and an optical particle sizer and counter (TSI OPS3330) for characterizing particulate size distributions from appliances operated over changing operational loads. In addition to size resolved measurements, we also collected total particle counts using a condensation particle counter (TSI CPC3775), $PM_{2.5}$ particle mass using a portable nephelometer (Thermo pDR-1500), and estimated mass of selected carbon fractions (e.g., black, brown carbon) using a 7-wavelength Aethalometer (AE33) and a 3-wavelength Absorption Spectrophotometer (Brechtel TAP). We also obtained estimates of the lung deposited surface area of potentially respirable PM was also obtained (Partector, NSAM).

7CB.9

In-field Emission Measurements of Common Incomplete Combustion Sources in Africa. DAVID PFOTENHAUER, Evan Coffey, Didier Muvandimwe, Christine Wiedinmyer, Rex Alirigia, Ricardo Piedrahita, Desmond Agao, Ernest Kanyomse, Abraham Oduro, Michael Hannigan, *University of Colorado, Boulder*

Anthropogenic emissions of pollutants in Africa still remain highly uncertain, and the contribution of residential emissions, domestic sources, and incomplete combustion is large. As part of the Research of Emissions, Air Quality, Climate, And Cooking Technologies In Northern Ghana (REACCTING), in-field emission measurements of trace gases and particulate matter (PM) were taken from 41 common combustion practices in the developing world. These sources include commercial cooking, charcoal making, kerosene lighting, trash burning, and roadside traffic sites. Emission Factors for carbon monoxide, carbon dioxide, and carbonaceous particulate matter were calculated. The emission factors will be used to update emission inventories and fingerprint sources for future studies related to personal exposure and apportionment of ambient pollution.

7CB.11

Chemical Characterization of Particles Emitted from Engine Operated by Natural Gas and Propane. SANNA SAARIKOSKI, Jenni Alanen, Hannu Vesala, Rasmus Pettinen, Mia Isotalo, Sampsa Martikainen, Matthew Bloss, Minna Aurela, Teuvo Maunula, Kauko Kallinen, Jan Torrkulla, Hilkka Timonen, Topi Rönkkö, Kati Lehtoranta, *Finnish Meteorological Institute*

Natural gas (NG) is used globally as a fuel in engines because of its good availability, competitive cost and lower CO_2 emissions compared to conventional liquid fossil fuels. However, also NG engines produce gas and particle emissions that can have effect on environment and human health. In terms of particle emissions, particle mass emissions from NG engines are small compared to conventional diesel engines because of lower soot particle formation in combustion but particle number emissions from NG engines, especially nanoparticle emissions, are not necessarily small. Although NG is most widely used fuel gas, in some power generation applications it is more advantageous to use other gas compositions, like ethane and propane, instead of NG that is composed mostly of methane. Changing the gas composition is likely to alter the emissions from gas combustion and also its environmental and health impacts. The first objective of this study was to examine particulate emissions from the engine operated by NG and propane. The second aim was to investigate the influence of different catalyst systems (oxidation catalysts and Selective Catalytic Reduction, SCR) on exhaust particles emitted from the gas engine.

Gas engine measurements were conducted at the engine test facility of VTT Technical Research Centre of Finland. A spark ignited passenger car engine adapted for NG and propane was used. Two different catalyst setups were tested of which the first one consisted of a combination of an oxidation and a Selective Catalytic Reduction (SCR) catalyst, and the other setup included only one oxidation reactor. Exhaust gas temperature was varied from 350 to 500 °C and exhaust gas flow was 80 kg/h or 40 kg/h. The chemical composition of exhaust particles was investigated by using a Soot Particle Aerosol Mass Spectrometer (SP-AMS, Aerodyne Research Inc.). Additionally, particle number concentration and particle size distribution were measured by a variety of instruments. The potential of gas engine exhaust to form secondary particles was examined by Potential Aerosol Mass (PAM) chamber.

Primary particulate mass emissions from the engine operated by NG and propane were very small. Primary particles were dominated by organic matter that consisted mostly of hydrocarbon compounds. Compared to primary emissions, secondary particulate mass emissions from gas engine were larger. Chemical composition of secondary particles was similar to NG and propane being dominated by sulfate (~50 %) and organic matter (~40 %), and followed by ammonium (~4 %) and nitrate (~2 %). However, the concentration and chemistry of secondary particles were dependent on the engine and catalyst conditions.

7CB.12

Properties of Carbon Particles Generated by Methane Decarbonization in Oxygen Deficient Gas Streams. Mohammad Javad Afroughi, Farjad Falahati, Larry W. Kostiuk, JASON S. OLFERT, *University of Alberta*

At a sufficiently high temperature, methane (CH_4) can be decomposed to solid carbon black ($C_{(s)}$), a feedstock for many industrial products, and hydrogen (H_2), which can be used as a carbon-free fuel. As such, methane decarbonization is viewed as a potential method to produce hydrogen (or heat or electricity if the hydrogen is used as a fuel) without CO_2 emissions. Furthermore, the solid carbon can be sold for use in industrial products; however, its value depends on the physical properties (i.e. size, morphology) of the carbon. Several methane decarbonization processes have been proposed including bubbling the methane through molten metal, heating the methane by a plasma, or in the hot products of combustion gases.

This study investigates the physical properties of carbon particles generated during decarbonization of methane in hot products of two different premixed flames. An inverted burner is designed to provide a rich, laminar, premixed flame of propane- and methane-air, with a total constant flow rate of 36.5 SLPM. The burner later injects methane co-flow to be decomposed within a closed quartz tube (20 cm in diameter and 68 cm in length). By placing ceramic blocks with axial concentric holes, a thermally insulated, reaction chamber of 4 cm diameter is created inside the tube. The formed products of decarbonization are discharged through an exhaust with two sampling branches. Measuring gaseous concentrations, a branch of products is dried and sent to a gas chromatographer (GC), while the other branch samples carbon particles with a nitrogen dilution system. Size distribution, effective density, and volatile mass fraction of particles are obtained with sequential arrangements of a differential mobility analyzer (DMA), catalytic denuder, centrifugal particle mass analyzer (CPMA), and condensation particle counter (CPC). Dilution ratios are calculated using simultaneously measured CO_2 concentrations in exhaust products and diluted samples. Axial temperature distribution in the reaction chamber is also measured by a K-type thermocouple.

Different flow rates of methane (0.5 to 5 SLPM) are injected in oxygen deficient gas stream of propane- and methane-air premixed flames, with maximum temperature of 1170 and 1135 °C, respectively, to be decarbonized. Results show that properties of generated particles are strongly dependent on type of the premixed fuel, and decarbonized methane flow rate. Generally, decarbonization using propane-air premixed flame produces larger particles with higher number concentrations, for a given injected methane flow rate; e.g. total particle number concentration and median mobility diameter increase from 1.27×10^8 to 1.69×10^8 cm^{-3} and from 21 to 58 nm, respectively, due to change of premixed fuel from methane to propane at a constant decarbonized methane flow rate of 0.5 SLPM. Furthermore, median diameter of size distribution is inversely proportional to decarbonized methane flow rate, and decreases from 58 to 18 nm (21 to 18 nm) following the injection of 0.5 to 5 SLPM of methane to the propane-air (methane-air) premixed flame. It is also notable that effective density and volatile mass fraction of particles are size-dependent and decrease from ~2000 to 500 kg m^{-3} and from ~0.55 to 0.35, respectively, with the increase in mobility diameter from 14 to 700 nm.

7CB.13

A nvPM Formation and Oxidation Semi-Empirical Model for Gas Turbines in Commercial Aviation. Joseph Abrahamson, RANDY VANDER WAL, *Penn State University*

Several semi-empirical relations have been developed to estimate nonvolatile particulate matter (nvPM) mass emissions from rich-quench-lean (RQL) style combustors employed predominantly in the current aviation fleet. The accuracy of such methodology has been hindered by inaccurate combustor conditions. Additionally, current relations are not optimized for direct cruise nvPM emission predictions and do not account for fuels, in particular alternative jet fuels with reduced aromatic contents. An improved semi-empirical kinetic based predictive relation has been developed for these purposes. Accurate engine conditions are based on proprietary engine cycle data for a common RQL style combustor. Nonvolatile particulate matter formation rates dependent on equivalence ratio, thrust, and fuel components are developed to accurately predict emissions across thrust settings and fuels. The new model captures both ground and cruise altitude emissions. To incorporate fuel effects hydrogen content is used as it encompasses all three fuel components: aromatics, paraffins and cycloparaffins. Predicted values are validated against field campaign data collected over a decade from NASA Langley’s Aerosol Research Group with inclusion of cruise data.

7CB.14

CAAFCER: Particle Number Emission Factors from In-Flight Aircraft Fueled with Jet A1 and Biofuel Mixtures. STEVEN TRAN, Jason S. Olfert, Anthony Brown, Fred J. Ghatala, *University of Alberta*

The aviation sector has begun using biofuels to reduce greenhouse gas (GHG) emissions in an effort to fight climate change. The use of biofuels also has impacts on aircraft particle emissions. The Civil Aviation Alternate Fuel Contrail and Emission Research (CAAFCER) project was designed to investigate the emission performance of high blend Hydrotreated Esthers and Fatty Acids (HEFA) biojet and conventional Jet A1 fuel in a real environment via flight emissions monitoring and fuel analysis from passenger airlines under contrail conditions. While the particle emissions of biofuels have been studied extensively in laboratory conditions (with emissions sampled from engines or stationary aircrafts on the ground), few studies have been undertaken with aircraft emissions sampled in the air during commercial (revenue) flights.

In CAAFCER, the source of emissions came from Air Canada A320 series aircrafts with NRC's CT-133 trailing behind to collect contrail data. The Air Canada flights were travelling between Toronto and Montreal. The Montreal-Toronto flights used the biofuel blend while the Toronto-Montreal flights used Jet A1 fuel. The CT-133 flew in and out of the contrails in order to capture contrail and background data. The NRC CT-133 was equipped with the necessary equipment to collect contrail and emissions measurements such as a TSI 3776 ultrafine particle counter (lower limit of 2.5 nm), TSI 7610 particle counter (lower limit of 10 nm), Thermo 42I NOx Analyzer, LII300 black carbon sensor, FSSP-100 ice particle sensor and LiCor 840A CO2 and water vapour sensor. A thermal denuder (Catalytic Instruments) with a bypass was installed upstream of the 3776 CPC. The thermal denuder allowed for the measurement of non-volatile particles and was only installed in-line to the 3776 CPC.

Particle number emission indices for particles greater than 2.5 nm (3776 CPC) and greater than 10 nm (7610 CPC) were calculated to evaluate the emission performance of Jet A1 and biofuel using the Fuel Flow Method 2 developed by Boeing. This method relates fuel flow to emission indices which are both publicly available. NOx emissions were used as a tracer to determine the dilution ratio of the contrail between the source aircraft and the CT-133 measurement aircraft. The dilution ratio was then applied to the concentration of particles measured by the particle counters to estimate the total number of particles emitted by the source aircraft.

Final results will include emission indices for both the 3776 CPC and 7610 CPC. The emission indices for total particles (volatile and non-volatile) greater than 10 nm will be calculated for the biofuel blend and Jet A1 fuel. The emission indices for particles greater than 2.5 nm will be calculated for both types of fuel as well as total and non-volatile samples for each type of fuel.

PM2.5 and Its Carbon Components Emitted from a Diesel Engine Generator Fueled with Waste Cooking Oil-based Biodiesel Blends. Jen-Hsiung Tsai, SHUI-JEN CHEN, Chia-Chin Wu, Kuo-Lin Huang, Jia-Twu Lee, Wen-Yinn Lin, Chih-Chung Lin, *National Pingtung University of Science and Technology*

Diesel particulate matter (DPM) is typically composed of carbon particles (soot) and numerous organic compounds produced by incomplete combustion. DPM will cause serious air pollution and human health problems and it is also one of the major sources of fine particles ($PM_{2.5}$) in many urban areas. Till now, the $PM_{2.5}$ from non-road diesel generators fueled by waste cooking oil-based (WCO) biodiesel blends has seldom been studied. In this study, a small diesel generator, fueled with three WCO-biodiesel blends (W0 (pure diesel), W20 (20% WCO-biodiesel + 80% diesel), and W40), was operated at 1.5 and 3.0 kW loads to investigate the $PM_{2.5}$ and its carbon components in the exhaust. The results showed that the $PM_{2.5}$ concentrations in engine exhaust ranged from 12.9–15.9, 11.3–13.2, and 12.5–14.7 mg/Nm^3, and averaged 14.2±1.44, 12.1±0.86, and 13.4±0.97 mg/Nm^3 using W0, W20, and W40, respectively, at 1.5 kW. At 3.0 kW, the high $PM_{2.5}$ levels were 23.2–27.2 (average: 25.2±1.69), 15.1–22.3 (average: 17.9±3.45), and 17.9–20.6 mg/Nm^3 (average: 19.2±1.23 mg/Nm^3) using W0, W20, and W40, respectively. The $PM_{2.5}$ emission reductions were 15.2% and 6.07% at 1.5 kW, and 31.8% and 23.8% at 3.0 kW, using W20 and W40, respectively. Under the two loads, the concentrations of $PM_{2.5}$-bound organic carbon (OC) and elemental carbon (EC) were 3.58±0.94 to 6.50±0.29 mg/Nm^3 and 9.12±0.38 to 16.2±0.87 mg/Nm^3, respectively, for using W0, which were lower than those for using W20 by 23.7–45.4% and 6.85–21.4%, respectively (OC = 2.73±0.66 to 3.55±0.69 mg/Nm^3 and EC = 8.50±0.14 to 12.8±2.87 mg/Nm^3), and those for using W40 by 17.0–38.5% and 4.69–38.5%, respectively (OC = 2.97±0.23 to 4.00±1.14 mg/Nm^3 and EC = 8.69±0.13 to 13.2±0.53 mg/Nm^3). On average, the total carbon (OC+EC) contributed ~88% (OC and EC: 22% and 66%, respectively) of the $PM_{2.5}$ mass concentration.

7CB.16

PM2.5-bound Metal Emission from a Diesel Engine Generator Fueled with Biodiesel Converted from Used Cooking Oil.

Jen-Hsiung Tsai, SHUI-JEN CHEN, Chi-Ying Hsieh, Cheng-Hung Tsai, Wen-Yinn Lin, Kuo-Lin Huang, Chih-Chung Lin,
National Pingtung University of Science and Technology

Many studies have confirmed that the use of appropriate proportion (~20 vol%) of the biodiesel converted from non-edible greases (e.g., waste cooking oil (WCO)) can effectively reduce the emissions of particulate matter (PM), traditional gaseous pollutants, polycyclic aromatic hydrocarbons (PAHs) and other pollutants of diesel engines. However, some poor-quality aluminum, copper or stainless cooking utensils may result in the presence of toxic metallic elements (e.g., Ni, and Cr) in recycled WCO. Therefore, the emission of particulate toxic metals from the combustion of WCO-based biodiesels needs to be investigated. This study presents the emissions of 21 metals (Na, Mg, Al, K, Ca, Ti, V, Cr, Mn, Fe, Ni, Cu, Zn, As, Sr, Mo, Cd, Sn, Sb, Ba, and Pb) in the emitted $PM_{2.5}$ from a small diesel generator, fueled with WCO-biodiesel blends under 1.5 and 3.0 kW loads, by adopting $PM_{2.5}$ cyclones to separate aerodynamic particle sizes ≤2.5 µm from the larger particles in the tailpipe stream. A brand of pure fossil diesel (W0) was adopted as the base fuel, and it was added by 20% and 40% WCO-based biodiesel to form W20 and W40 blends, respectively. The results showed that the mean concentrations of the sum of 21 metals (ΣMetals) on the $PM_{2.5}$ in the exhausts for using the tested fuels followed the order W40 (60.8–109 $\mu g/Nm^3$) < W20 (66.9–110 $\mu g/Nm^3$) < W0 (81.7–142 $\mu g/Nm^3$), despite the generator loadings. Additionally, the mean contents of ΣMetals were in the order D100 > W20 > W40 at 1.5 kW and W20 > D100 > W40 at 3.0 kW. Regardless of fuel blends, the mean concentrations and contents of ΣMetals on $PM_{2.5}$ increased as the engine loading increased. The metal elements in $PM_{2.5}$ sample were dominated (over 90% mass of total metals) by Na (3.20%), Mg (5.31%), Al (4.65%), K (19.0%), Ca (20.9%), Fe (10.5%), and Zn (31.5%). The major contents of the rest (minor) metals were Ni (2.14%), Ti (0.74%), Cr (0.57%), Mn (0.55%), and Mo (0.41%). The reduction rates of ΣMetals for using W40 were 25.6% and 23.0% at 1.5 and 3.0 kW, respectively, while for using W20 the corresponding data were 18.0% and 22.6%, respectively.

Origin of Soluble Iron from Low-emitting Automobile Exhaust. JOSEPH SALAZAR, Benton Cartledge, Lynn Russell, Allen Robinson, Greg Drozd, Allen H. Goldstein, Brian Majestic, *University of Denver*

Soluble iron has been found to be a limiting reagent for phytoplankton in most of the southern oceans. Phytoplankton is a vital part of the ocean's ecosystem as it is involved in CO_2 uptake and nitrogen fixing. Thus, understanding iron geochemical cycle is essential to understanding the earth's oceans and atmospheric interactions. Soluble iron has been correlated to oxalates, nitrates and sulfates resulting in the hypothesis that iron is solubilized through an acid processing mechanism. Despite the correlations in field studies, these relationships have not been reliably proven in the laboratory. Previous field studies have linked soluble iron over the ocean to combustion sources and, in general, relative soluble iron tends to be greater in urban areas. To understand the origin of soluble iron in urban areas, PM was collected from the tail pipes of low emitting gasoline vehicles at the CARB dynamometer facility using the California Unified (UC) Drive Cycle. The PM was collected from the exhaust pipe and analyzed for inorganic ions, EC/OC, total and soluble metals, functional groups, and GC-MS was used to quantify the class of 11 to 18 carbon intermediate volatility organic compound (IVOC), ultimately categorized as alkane (ALK), single ring aromatic (SRA) and general (GEN) for each number of carbon. The results showed that the tested automobile emissions have a high fraction of percent iron solubility ranging from 0% - 81.9% with an average of 26.7%. This is a significant increase compared to crustal sources where the soluble iron is approximately 1% of total iron. The samples were analyzed by x-ray near edge absorption structure (XANES) spectroscopy, which confirmed that only Fe(III) was present in the samples and, thus, any increased solubility was not due to the presence of the more soluble Fe(II). Correlation of soluble iron to sulfate was insignificant (R2 = 0.157), as was the correlation to every measured chemical component, except one class. Soluble iron was highly correlated to the C11 - C18 IVOCs, with R2 values as high as .981 for IVOC SRA-C14. These results imply that the large driver in soluble iron from gasoline vehicle emissions is related to the organic fraction of the PM, suggesting that further studies are required to study metal-organic interactions in PM.

7CB.18

On-Line Measurements of Selenium Emissions from an Operating Coal Fired Power Plant. Edward Fortner, Joseph Roscioli, Jordan Krechmer, Manjula Canagaratna, Scott Herndon, JOHN JAYNE, *Aerodyne Research, Inc.*

Coal fired power plants are a significant emission source of criteria gas pollutants as well as trace elements. Volatile toxic elements pose special concerns since they may not be efficiently removed by existing gas phase control measures in modern power plants and can therefore pass through the different process streams and be emitted into the environment. While some elements such as sulfur and mercury have regulatory emission controls imposed others do not. One such element is selenium which is believed to exist mostly in the oxidized form. Selenium dioxide has received special attention since it has volatility characteristics that allow it to partition between the gas and condensed phases at typical flue gas exhaust temperatures. The relatively high volatility has made it difficult to quantify the fate of selenium using standard analytical filter based collection methods. Prior measurements of selenium in the flue gas have shown wide variability in material balance closures indicating an incomplete understanding of the behavior of selenium in the process stream. Here we present results from a field measurement project that demonstrates the use of advanced technology instrumentation for the real-time, on-line detection of trace pollutants from an operating power plant. Both mass spectrometric and infra-red spectroscopic instrument systems were used to measure the concentrations of selenium dioxide in the flue gas and to estimate gas-particle partitioning, emission indices and removal efficiencies. To our knowledge this was the first time such measurements have been made at an operating power plant with these instrument technologies and demonstrates their applicability for use in collecting chemically speciated data from power plant streams in real-time.

7CB.19

Collection Characteristic of Diesel Nano-Particles in an Electrostatic Precipitator: Experiment Using Residual Fuel Oil and Light Fuel Oil. HIDETOSHI SAWANO, Akinori Zukeran, Yasumoto Koji, *Kanagawa Institute of Technology*

Diesel engines have been extensively used as a generator, an automobile or an agrimotor due to low CO_2 emission. However, their exhaust gases contain air pollutants, such as NO_x and particulate matter (PM). It is known that nano-particles are included in PM. SO_x is also included in exhaust gas, when residual fuel oil is used.

The purpose of this study is to remove PM using an electrostatic precipitator (ESP). In particular, the relationship between nano-particle collection efficiency and the particle diameter was investigated for emission gas from diesel engine with residual fuel oil and light fuel oil.

The experimental system consisted of a diesel engine (displacement 400cc) and an ESP, and residual fuel oil (ENEOS LSA heavy oil (01)) or light fuel oil (ENEOS gas oil) were used for the diesel engine. The ESP has a needle-to-cylinder electrode structure with a metal cylinder with an inner diameter of 58 mm and a stainless steel needle electrode with a diameter of 1.6 mm (tip angle 14 °, curvature radius 22 μm). The voltage applied to the needle electrode was DC-16 kV.

A portion of the gas was drawn at the gas temperature of 160℃ and 10-hold diluted by the diluter at the same temperature of the gas. After cooling to the room temperature, the particle concentration was measured using a scanning mobility particle sizer (SMPS, TSI, Model 3936). SMPS can measure the particle concentration for the particle diameter between 5.9 and 250 nm. The collection efficiency η was calculated by equation (1):
$(1-(N/N_0))\times 100\%$ (1)
where, N is particle density after applying the voltage, and N_0 is particle density before applying the voltage.

When residual fuel oil was used for a diesel engine, the particle size distribution at the voltage of 0 kV had a peak of approximately 6.0×10^6 parts/cm^{3}at the particle size of 57 nm. At the voltage of -16 kV, the particle concentration at 57 nm decreased to approximately 2.2×10^5 part / cm^3. The collection efficiency was greater than 95%. This is due to electrostatic precipitation effect. However, the concentration for the particle size less than approximately 20 nm increased at the voltage of -16 kV in comparison with that at 0 kV. Thus, the experiment using the light fuel oil was carried out in order to investigate this cause. As a result, the particle size distribution at the voltage of 0 kV had a peak of approximately 6.6×10^6 parts / cm^3 at the particle diameter of 71 nm. At a voltage of -16 kV, the particle concentration at 71 nm decreased to 0.8×10^6 parts / cm^3 due to the electrostatic precipitation effect. However, particle concentration for the particle diameter less than 20 nm did not increase.

It is known that fine particles are generated by ion-induced nucleation when corona discharge is generated in the gas included SO_2. Analysis of the components in the exhaust gas revealed that the SO_2 concentration in the exhaust gas using residual fuel oil was 37 ppm, although it was 2 ppm in the case of light fuel oil. Therefore, the increase the concentration for particles diameter less than 20 nm in the exhaust gas using residual fuel oil was due to ion-induced nucleation.

However, the total number collection efficiency in the exhaust gas using the residual fuel oil was 87%, and the ion-induced nucleation did not influent on the total collection efficiency. It is also known that the collection efficiency of fine particles can be improved by increasing the collection electrode length.

7CB.20

Sizing Sub-10 nm Particles from Engine Emissions. JOONAS VANHANEN, Jenni Alanen, Kati Lehtoranta, Sanna Saarikoski, Minna Väkevä, Topi Rönkkö, *Airmodus Ltd.*

It has been shown that a big fraction of the particle number concentration of an engine emission can be in sub – 10 nm size range (Rönkkö et al. 2017). The measurements conducted by Alanen et al. (2015) have indicated that some of these particles have a solid core as small as 2 nm in diameter. In this study, we measured nanoparticle number concentration and mean diameter from a natural gas engine using a modified Airmodus A20 butanol Condensation Particle Counter. In our measurements the particle mean sizes from engine emission were often between 3-6 nm. The mean diameters measured with the modified A20 bCPC agreed with mean particle diameters from SMPS measurement.

The A20 is a laminar, one flow instrument that has 5 nm lower cut-point with factory settings of 1 lpm flow rate, 39oC saturator temperature and 15oC condenser temperature. We have increased the flow rate up to 2.2 lpm, the saturator temperature up to 44oC and lowered the condenser temperature down to 10oC. The increase of flow rate lowers the diffusional losses especially for the smallest particles and the higher temperature difference between the saturator and the condenser increases the highest supersaturation for the n-butanol vapor inside the instrument. This makes it possible to activate and grow smaller particles with smaller losses. The grown particles are detected using light scattering. Every particle creates a pulse that is, in some extent relative to the initial size of the sampled particle (Marti et al. 1996). Smaller particles activate later inside the instrument than the bigger ones and thus have less time to grow. This creates smaller droplets and smaller measured pulses. The instrument was calibrated using silver nanoparticles in the size range of 2.3 nm to 40 nm. The 50% cut-off for silver particles was 3.1 nm, but the instrument was still capable of counting 20% of the 2.3 nm. Airmodus A20 measures the mean pulse width of the optical pulse created by the grown particle inside the CPC within the sampling time of 1 second. It was found that this mean pulse width corresponds nicely with the sample particle size from 3 to 10 nm. If there is no significant signal from particles larger than 10 nm, this information can be used to measure mean size of particles. This new method of using the mean pulse width enables the measurement of particle size and concentration with 1 Hz sample rate. Other instruments capable of measuring size distributions down to 3 nm usually have sample rate of a couple of minutes. In the future this method will be developed further to include full pulse width spectra for aerosol size distribution measurements.

Hygroscopicity Measurements near Cloud Indicate Aerosol-Cloud Processing without Interrupting Ambient Measurements. STEPHEN NOBLE, James Hudson, *Desert Research Institute*

Transformations of atmospheric aerosols occur through processes within clouds. Clouds process aerosols in three ways; aqueous oxidation of trace gases within the droplets that add soluble material (chemical); collision and coalescence of droplets to combine soluble material from the aerosol (physical); and Brownian capture of interstitial particles to add soluble or less soluble material (physical). As most droplets evaporate, this leaves an altered particle from the one initially activated. This resulting particle is larger and more easily activates at lower supersaturations in subsequent cloud cycles. This activation improvement impacts cloud droplet number and size, and drizzle amount (Hudson et al., 2015; Hudson et al., 2018), which have implications for climate. Aerosol-cloud processing separates the processed (accumulation mode) and unprocessed (Aitken mode) aerosol. The resulting bimodal distributions have been observed in particle size measurements (Hoppel et al., 1986) and cloud condensation nuclei (CCN) measurements (Hudson et al., 2015). Hygroscopicity (κ) can be determined from particle size and CCN distributions, measured by critical supersaturation. Overlaying particle size and CCN distributions and tuning the κ value to produce agreement gives κ for the distribution. Separate tuning for Aitken (unprocessed) and accumulation (processed) modes provides κ for each mode. Differences in processing type are highlighted by κ differences between the two modes. Two aircraft field projects; a polluted stratus cloud study (MArine Stratus/stratocumulus Experiment, MASE), and a clean summertime cumulus cloud study (Ice in Cloud Experiment-Tropical, ICE-T); provide κ of the two modes. Differential mobility analyzers measured particle size distributions while the Desert Research Institute CCN spectrometer measured CCN distributions in both projects. In ICE-T, 60% of bimodal distributions had the same κ for both modes while in MASE only 26% had the same κ. This indicates collision and coalescence dominating in ICE-T where CCN with similar κ were combined through droplet coalescence. However, in MASE chemical processing via aqueous oxidation dominated because the two modes had different κ for 74% of bimodal distributions. This is consistent with Hudson et al. (2015). Generally, adding hygroscopic material through cloud processing makes processed κ greater than unprocessed κ. However, even when unprocessed κ is high, aqueous oxidation adds material that is less soluble (sulfates added to sea salts) and the resulting processed κ tends towards κ of the added material. This was evident in MASE. Cloud types in these projects appear to affect cloud processing type where larger vertical motions (W) in cumulus clouds create larger droplets that coalesce, while shallow stratus clouds with limited W promote chemical processing. More investigations among cloud types are needed. Here, the evidence suggests both types of processing existed to some extent in both projects. This new method to determine hygroscopicity is continuous; i.e., no interruptions of ambient particle size or CCN measurements; but may not be as exact as other methods. But, this κ measurement allows for investigation of aerosol evolution due to these natural cloud processes while providing information about relative particle hygroscopicity and can be performed after measurements have already been taken; i.e., used on archived data.

Ccn Characteristics Observed at a High Altitude Site in Western Ghats. ARSHITHA ANAND K.A., R.S. Maheskumar, *Banaras HIndu University.*

Atmospheric aerosols which serve as cloud condensation nuclei (CCN) are key elements of hydrological cycle and climate change. In the present work, monthly and seasonal variation of CCN characteristics have been studied at Mahabaleshwar (1348 m AMSL) site in Western Ghats, using one year (December 2014- October 2015) of observations.

The study has been done in two sections first, we have seen how the CCN concentration varies with different supersaturation for different months and seasons during both daytime and nighttime separately. Later monthly and seasonal behavior of diurnal variation of CCN has been studied. CCN concentration shows higher values during both daytime and nighttime. Considering daytime and nighttime separately the monsoon season shows higher concentration during daytime and pre-monsoon shows higher concentration during nighttime. During the winter season, the Anthropogenic aerosols are dominant and due to calm wind during pre-monsoon and winter, the particles are less dispersive so it will be mainly confined to small area covering the study region. The seasonal dust is one the other reason for the increase in CCN concentration during pre-monsoon season. In the monsoon, the CCN concentration shows higher values because of the long range transport from the Arabian sea due to strong south-westernly wind. This result suggest that CCN concentration can be increased because of the emission of the aerosol particle from natural source such as forest, and also it can be increased because of anthropogenic activities. Overall analysis showed that CCN concentration was higher over this high altitude site despite of dominant sink process such as cloud scavenging and washout mechanism indicating local emission.

7CC.3

CCN Activity and Particle Growth of Aging Diesel Exhaust Particles. Humphrey Chukwuto, FRANK BOWMAN, *University of North Dakota*

Diesel exhaust particles emitted into the atmosphere undergo aging that changes their physical and chemical properties, but these processes are complex and not well understood. Laboratory chamber experiments were conducted to investigate the aging of diesel exhaust in the presence of UV light, ammonium sulfate particles, and/or α-pinene vapors. Particle growth and changes in number concentration and size distribution were monitored with a SMPS. Changes in CCN activity were measured with a CCN counter. Results from dark experiments with diesel exhaust alone showed no significant secondary organic aerosol formation and diesel exhaust particles that remained CCN inactive. Aging experiments with UV radiation resulted in a significant increase in particle mass, with deposition-corrected particle mass after 4 hours that was 20-60% higher than the initial mass of freshly emitted diesel soot particles. CCN activity also increased over time indicating that photooxidation of diesel exhaust vapors produces SOA more hygroscopic than the freshly emitted diesel particles. The addition of α-pinene to diesel exhaust in UV aging experiments further enhanced both CCN activity and SOA formation. Experiments with ammonium sulfate particles showed no discernible effect on SOA formation for either diesel exhaust alone or diesel exhaust/α-pinene mixtures. CCN activity measurements were consistent with a largely external mixture of hygroscopic ammonium sulfate particles and non-hygroscopic diesel soot, coated with moderately hygroscopic SOA. The results from this study underscore the importance of aging via photooxidation of SOA precursors and mixing with water-soluble particles in transforming hydrophobic soot into more CCN-active particles.

Characteristics of Cloud Condensation Nuclei in an Urban Region of Central Taiwan. TA-CHIH HSIAO, Wei-Jen Hsieh, Neng-Huei Lin, Chun-Chiang Kuo, *National Central University*

Cloud condensation nuclei (CCN) constitute a crucial fraction of atmospheric aerosols (Burkart et al., 2011). The physical and chemical characteristics of CCN is closely related to cloud development and precipitation process (Andreae and Rosenfeld, 2008). In urban region, traffic emissions, containing fresh small particles and hydrophobic substance, could be the major source for local air pollutions (Souto-Oliveira et al., 2016) and influencing the aerosols hygroscopicity and CCN's characteristics. Moreover, as aerosols released to atmospheric environment, different "aging processes", such as condensation, coagulation and oxidation, would change its physiochemical properties and enhance homogeneity as well as hygroscopicity of particles (Gunthe et al., 2011).

In this study, CCN's characteristics in Taichung city, which is the major metropolitan region in central Taiwan, was quantified by the activation ratio (AR = CCN number concentration/condensation nuclei concentration) during Sept. 2017 to Feb. 2018. The experimental hygroscopicity, κexp, proposed by Petters and Kreidenweis (2007) under the scheme of Köhler theory was further derived using AR and collocated particle size distribution (PSD) measurements. On the other hand, κchem was estimated based on the real-time aerosol chemical compositions, which were monitored by a PILS-IC system. The analysis between AR, particle size and hygroscopicity revealed two distinct groups of CCN characteristics in central Taiwan. One demonstrated a positive correlation with particle size and AR, and the other presented a relatively weak correlation. This suggests particle size and its chemical composition could both play important roles in aerosol's hygroscopicity and CCN's activity. Our data also show that κchem and AR is a function of wind direction (WD) and wind speed (WS), generally with higher values associated with winds from the south. The potential source contribution function (PSCF) analysis is further employed to investigate the contributions of potential local emission sources.

Large Indirect Radiative Effects of Smoke in the South-east Atlantic. HAMISH GORDON, Paul Field, Ken Carslaw, *University of Leeds*

Smoke from African fires mixes into clouds near Ascension Island in the south-east Atlantic, substantially influencing their radiative properties over a vast swathe of ocean[1]. The area of mixing coincides with the transition from stratocumulus to cumulus clouds, so any effects of aerosols on cloud cover are likely to be particularly important[2].

The clouds are strongly influenced by droplet concentration and liquid water path, both of which are difficult to represent in models. The droplet concentration requires accurate horizontal and vertical positioning of realistic aerosol plumes. In regional or global models, the liquid water path depends on correct representation of the boundary layer and on the sub-grid cloud fraction. Evaluation of the droplet concentration can be challenging as satellite retrievals may be compromised by above-cloud aerosol, which itself affects the properties of the clouds[3]. However, the recent CLARIFY campaign provides key in-situ data and fresh insights on how to deal with these issues.

This presentation will show how the aerosol-cloud interactions in this region can be represented in a convection-permitting regional Unified Model simulation driven by the HadGEM-UKCA global aerosol-climate model. The 4km-resolution regional simulation has two-moment aerosol driving two-moment cloud microphysics (the CASIM scheme[4]). In our model, the presence of smoke aerosol leads to a substantial increase in cloud droplet number, and also to significant effects on the cloud microphysics and boundary layer dynamics. We will highlight key challenges in simulating the stratocumulus-to-cumulus transition in the tropical Atlantic with large-scale models, for example the representation of aerosol mixing into the boundary layer. We will also show comparisons of our model to measurement data from the CLARIFY campaign.

7CC.6

Cloud Effects on the Aitken and Accumulation Modes. JAMES HUDSON, Stephen Noble, *Desert Research Institute*

At SGP correlation coefficients, R, between remotely-sensed cloud fraction, cf, and time-lagged surface aerosol mean diameter (md) increased from zero (simultaneity) to maxima for aerosol ~five hours after cf. Delay was due to transit from cloud altitudes to surface. Peak Rs were greater for instruments with greater sky coverage (pyranometer gridded network [PGN]; total sky imager [TSI]) than ceilometer. But TSI and PGN operated only during daylight. Ceilometer cf-md Rs were also positive during daylight but negative at night. All three instrument peak Rs were also positive for cf-Aitken (< 100 nm; R = 0.54, 0.60 and 0.65; two-tailed probabilities, P2 < 10^{-8} for ceilometer [daylight], TSI and PGN, respectively) and accumulation mode md (> 100 nm; R = 0.27, 0.42 and 0.38; P2 4×10^{-5}, < 10^{-8}, < 10^{-8}, respectively). Negative peak Rs for cf-Aitken concentration were -0.30, -0.36, -0.35; P2 = 2×10^{-6}, < 10^{-8}, < 10^{-8}, respectively. Positive peak Rs for cf-accumulation concentrations were 0.23, 0.34, 0.34; P2 4×10^{-4}, 3×10^{-8}, 3×10^{-8}, for ceilometer, TSI and PGN, respectively.

Lagged md responses to cf > median cf steadily increased for ~five hours whereas lagged md responses to cf < median cf steadily decreased by similar md for ~five hours. When this was analyzed for consecutive hours of cloudiness or clearness, peak md increased/decreased by greater amounts.

More accumulation mode particles with larger sizes for greater cloudiness is consistent with aqueous oxidation, coalescence and Brownian scavenging by cloud droplets. These cloud processes thus account for the positive 0.47 R (P2 < 10^{-8}) between accumulation mode concentrations and sizes.

Negative Rs for cf-Aitken concentrations indicate more photochemical production for less cloudiness. Positive cf-Aitken size Rs indicate that initial photochemical particles are small. Brownian capture of cloud-interstitial particles also reduces Aitken concentrations, especially smaller Aitken particles because of their greater Brownian motion. This increases sizes of remaining Aitkens. Many Aitkens are converted to accumulation particles. The sizes of some larger Aitken particles are also increased by aqueous chemistry on those that nucleated cloud droplets. All of these processes make the negative R for Aitken concentration versus size (R = -0.42, P2 < 10^{-8}).

Separating Aitken concentrations by each hour of the day and according to above or below mean cf, all three instruments (six plots) show similar concentrations (~2000 cm^{-3}) for the first daylight hours. But after 10 AM concentrations increase by a factor of three for all plots except PGN cf > median cf, which remains below 2000 cm^{-3} all day. For cases when all three instruments simultaneously report cf > median cf, Aitken concentrations remained below 2000 cm^{-3} all day. The smaller numbers of cases when ceilometer or TSI cf > median cf but PGN cf < median cf cause the high midday ceilometer and TSI Aitken concentrations for cf > median cf. The consistently low PGN cf > median cf Aitken concentrations indicate that PGN greater sky coverage better represents the cloud conditions that inhibit photochemical Aitken particle production. The more local TSI and ceilometer sky coverages, therefore, misrepresent conditions most favorable for photochemical Aitken particle production.

Six similar hourly plots of accumulation mode concentrations also divided according to median cf are nearly identical for the three instruments; i.e., low accumulation mode concentrations for low cf throughout the day and factor of two higher concentrations for high cf with early afternoon peaks. Thus, the accumulation mode responds more to local cloudiness whereas the Aitken mode responds to more widespread clear skies.

7CC.7

Cloud and Aerosol Optical Analysis for Temperate Zona. Ibtissam Marsli, MOHAMMED DIOURI, Djamaleddine Chaabane, *Atmospheric Physic, LME, University of Oujda, Morocco*

Cloud and aerosol are of high importance in understanding the variability of radiative balance; they can also clarify the atmospheric evolution and remove the still significant uncertainties in climate change models. From the AERONET/PHOTONS network the data processing of about thirty sites distributed over the temperate zone allowed a precise characterization of the optical properties of clouds (optical thicknesses and occurrence frequencies) and aerosols (PSDs, single scattering albedo, optical depths and radiative forcing). This study concerns the analysis of data of the following sites: Maryland (38.99 °N, 76.83 °W), ARM_Graciosa (39.09°N, 28.02°W), La_Laguna (28.48°N, 16.32°W), Carpentras (44.08 °N,5.05°E), Weizmann_Institute (31.90°N, 34.81°E) , CEILAP-RG(51.60°S, 69.32°W) and Durban_UKZN(29.81°S, 30.94 °E). These seven sites are a sample representing the temperate zone from 77°W to 35 °E.

The histograms of the occurrence frequencies of the cloud optical depths reveal the dominance, as in the equatorial zone, and of identical way, of those included between 20 and 100 relating to low clouds as Stratus and Altostratus with 57%. For values below 20, the histograms are different and the appearance is dependent on the weather conditions of the considered region. The seasonal average of aerosol PSD show larger amplitudes with a maximum total volume concentration of 110, 58 10-3 (µm3/µm2) observed in Southeast of Mediterranean Sea. The corresponding accumulation and coarse modes determined for all the sites show median radii near 0.17 and 2.56 µm respectively.

The spectral time series (0.87 and 0.44µm) of the aerosol single scattering albedo appear to be relatively similar and vary on average between 0.6 and 0.98; this variability can be explain by the meteorological conditions of each region and local air pollution. The aerosol radiative forcing shows a tendency towards low local cooling, with annual average values near -125 W/m2 at the bottom and -15 W/m2 at the top of the atmosphere. The monthly averages of aerosol optical depth at 0.5 µm shows that the highest values are often record on summer with a maximum reaching 0.4. As on Equatorial area, the time series of the occurrence frequencies of the aerosol optical depths and those of the clouds indicate certain links to be confirm by a statistical approach, which requires a long-term monitoring.

7CC.8

Presence of Photosynthetic Microorganisms in Clouds. KEVIN DILLON, Pierre Amato, Martine Sancelme, Valdis Krumins, Anne Marie Delort, Donna Fennell, *Rutgers, The State University of New Jersey*

Clouds contain diverse microbial assemblages. Previous work has demonstrated that some heterotrophic microorganisms are active in clouds and have an impact upon cloud water chemistry. Photosynthetic microorganisms (cyanobacteria and algae) were also shown to be present. However, their diversity and activity as primary producers, i.e. as CO_2-fixing organisms, is still poorly characterized in clouds. To date, no photosynthetic isolates from clouds have been reported. Cloud water was collected at the puy de Dôme meteorological station (1465 m, France) and used to establish photosynthetic enrichments. Enrichments were initially incubated at 20°C. Once the enrichments were established, they were grown at ≈22°C, 15°C, and 4°C under 75 µE m^{-2} s^{-1} of light. These phototrophic microorganisms had a higher growth rate at 15°C, a relevant temperature for clouds, thus demonstrating the possibility that these are active in clouds. This is the first reported culturing of photosynthetic microorganisms from clouds. Current work is underway to obtain axenic photosynthetic cultures and to evaluate the diversity and activity of photosynthetic microorganisms in the atmosphere.

7CC.9

Hazardous Ice Cloud Avoidance Using Airborne LiDAR Remote Sensors. RICHARD STONE, Justin Fisher, *Sigma Space Corporation*

One particularly costly problem confronting manned and unmanned aircraft operations is icing. Current systems today can only detect icing once an aircraft is in cloud. These methods also do not provide sufficient information about large supercooled water droplets >50 µm) that jeopardize flight by “bleeding” back from the leading contact edges and freeze on the wings and airframe. Better measurements of cloud characteristics and identification of icing potential using remote sensing techniques can reduce icing hazards and threats before an aircraft encounters icing.

RHS Consulting operates an aircraft equipped with a side-looking radiometer (Radiometrics), a Mini Micro Pulse LiDAR (Sigma Space Corporation), and a cloud droplet measurement system (Droplet Measurement Technologies). This plane routinely flies in icing conditions and is being used to investigate winter storm systems by collecting data from each of these systems to investigate instrument performance.

Recent data from these flights shows that Micro Pulse LiDAR measurements by themselves, are sensitive to supercooled liquid and mixed phase clouds at distances up to 10 km, and offer the advantage of direct range observations that do not require ancillary data sets to produce cloud liquid water contents. They also offer the high potential to directly measure hydrometeor particle size distributions. Thus the Micro Pulsed LiDAR technique offers great potential for providing a small low cost solution for detecting icing hazards in supercooled liquid water and mixed phase clouds at distances up to 10km or more. Measurements from the latest flights will be presented and discussed.

7CC.10

The Cloud Feedback on the Heating Rate of Black Carbon and Brown Carbon. FERRERO LUCA, Grisa Mocnik, Gregorič Asta, Cogliati Sergio, Colombo Roberto, Rizzi Cristiana, Di Liberto Luca, Barnaba Francesca, Gobbi Gian Paolo, Bolzacchini Ezio, *GEMMA Centre, DISAT, University of Milano-Bicocca*

Black carbon (BC) and Brown Carbon (BrC) absorb sunlight and heat the atmosphere[1]. The heating rate (*HR*) can be determined from the divergence of the net radiative flux with altitude (vertical profiles) or from the modelling activity; however, its determination is, up to now, too sparse. Moreover, it does not account for light-absorbing-aerosol (LAA) speciation and for the influence of different sky conditions in the atmospheric layer below clouds[2,3]. This work applies a new method[4] to experimentally determine (at high time resolution) the *HR* induced by LAA in a atmospheric layer. Highly-time resolved measurements of *HR* were apportioned in the context of LAA species (BC, BrC), sources (fossil fuel, FF; biomass burning, BB)[5], and as a function of cloudiness.

Multi-wavelength aerosol absorption measurements were coupled with spectral measurements of the direct, diffuse and surface reflected radiation using: 1) Aethalometer (AE-31, Magee Scientific, 7-λ), 2) Multiplexer-Radiometer-Irradiometer (diffuse, direct and reflected radiance: 350-1000 nm in 3648 spectral bands), 3) a meteorological station (LSI-Lastem) including a full set of radiometers, 4) Lidar Ceilometer (CHM 15k „NIMBUS“ was used for the determination of cloud base height and its vertical depth; www.alice-net.eu), 5) condensation and optical particle counters (TSI 3775 and Grimm 1.107), 6) low volume sampler (FAI Hydra, $PM_{2.5}$ and PM_{10}).

To understand the importance of sky condition on direct, diffuse and reflected component of *HR* (HR_{dir}, HR_{dif}, HR_{ref}) the fraction of sky covered by clouds (oktas)[6] and the cloud type were considered. Cloud types were classified based on radiometric, spectroradiometric and lidar measurements[7] into several classes in function of cloud base height: 1) low level (<2 km) stratus, cumulus and stratocumulus; 2) mid level (2-7 km) altostratus, altocumulus; 3) high level (> 7 km) cirrus, cirrocumulus-cirrostratus; 4) clear sky conditions.

More than one year of 5 min data (March 2015 - November 2016) of *HR* were collected in Milan (Po Valley). The *HR* showed a clear seasonal behavior (winter: 1.83±0.02 K day^{-1}; summer: 1.04±0.01 K day^{-1}) with a daily cycle characterized by higher values in the morning (than in the afternoon) following the BC-BrC concentrations. On average (one year) the BC accounted for 1.05±0.02 K day^{-1} while the remaining 0.15±0.01 K day^{-1} was due to BrC.

Most important, the *HR* varied in different sky conditions, from 1.75±0.03 K day^{-1} in clear sky to 0.43±0.01 K day^{-1} in complete overcast (annual averages). Also the kind of radiation involved in the *HR* varied with sky conditions. For example, in clear sky conditions HR_{dir} was higher than HR_{dif} and HR_{ref} accounting on average for the 55±5% of total HR and leading alone to a HR_{dir} of 0.49±0.01 K day^{-1} in summer and of 2.04±0.03 K day^{-1} in winter. In cloudy conditions the only efficient component was HR_{dif} (82±1% of total *HR*; from 0.28±0.01 K day^{-1} in autumn to 0.49±0.01 K day^{-1} in winter). Thus, clouds have a very important feedback also on the aerosol direct radiative effect.

Cloud types were investigated also considering their effect on radiation spectrum striking on LAA characterized by different absorption Angstrom Exponent (AAE of BrC and BC). Particularly, both clear sky and cirrus conditions showed an impinging spectrum of diffuse radiation peaking in the blue region exerting a highly efficient interaction with BrC (with an average AAE of 3.66±0.03).

Thus, in clear sky and cirrus conditions the HR_{BrC} accounted for 11.4±0.6% of the total *HR* while this percentage decreased just to 2.8±0.8% in cloudy cases, as stratus, cumulus, stratocumulus, altostratus, altocumulus. To investigate the role of clouds, the variability of *HR* due to the radiation was decoupled from that due to LAA concentrations by normalizing it for unit mass of BC. Results showed the strongest impact on *HR* by low level cumulus clouds, which (according to lidar data) form on the top of the mixing layer in late spring.

Characterization of Phase Changes in Clouds Using Hyper-spectral LIF-LIDAR. OFIR SHOSHANIM, Adva Baratz, *Israel Institute for Biological Research (IIBR)*

Cloud physics have great influence on global climate and Earth's energy budgets, however their empirical research is of great challenge. The dynamics of the formation and disappearance of droplets is governed by a critical thermodynamic balancing between atmospheric composition and its micro-meteorology. When raindrops are formed under such conditions, while falling through the atmospheric boundary layer, a cleaning air might occur due to droplet-aerosol coalescence. Since research in situ is the only way to fully conserve the atmospheric condition and thermodynamics, the optimal way to interrogate such processes in the atmosphere is by remote sensing.

The research presented here makes use of a fluorescent amino-acid molecule (Tryptophan) as a nuclei-bio-marker to interrogate the phase of a cloud. Its spectral signature in dry- or wet- form, allows to follow the phase changes and dynamics of the cloud using laser induced fluorescence LIDAR (LIF-LIDAR)[1]. The sensitivity to the spectral shifts and the anisotropy of the material's fluorescence is achieved in this work by exploiting the benefits of the hyper-spectral LIF-LIDAR which is based on an intensifier CCD (ICCD) sensor in a non-conventional way. We utilize this hyper-spectral LIF-LIDAR to measure the fluorescence spectra of aerosols (1-20 µm) from a distance of ~160 meters away. The back fluorescence from the aerosol phase is followed by UV photo-excitation (4th order of Nd$^+$YAG laser-266 nm) and detected simultaneously for both VV & VH polarization components. We also develop a technique of photon counting, which has been implemented on a full chip-image, to reduce the noise to signal ratio in the ICCD readout. The experimental setup includes a 3 sqrm aerosol-cell which is instantaneously controlled and monitored, following the fluorescence anisotropy, the elastic depolarization backscatter, the peak pulse power (pre- and post-cell), the generation and size classification of the aerosol phase, and the ambient conditions inside the cell.

This study demonstrates gradual vanishing process of the spectral Stokes shift due to the drying process of the Tryptophan aerosol inside the cell. This drying is also responsible for the increase in the fluorescence anisotropy of the suspended Tryptophan molecules. The research shows that remote sensing with hyper-spectral detection allows tracking phase changes of aerosols in the atmosphere. Such LIF-LIDAR setup increases the spectral perceptivity of aerosol remote sensing and demonstrate a novel technique to the study of cloud dynamics.

Aerosol-Cloud Measurements during the NASA NAAMES Campaign: Summary of Data and Cloud Droplet Sensitivities.

RICHARD MOORE, Ewan Crosbie, Luke Ziemba, Mary Kacarab, Athanasios Nenes, Gao Chen, Johnathan Hair, Chris Hostetler, Claire Robinson, Michael Shook, Kenneth Thornhill, Edward Winstead, Bruce Anderson, *NASA*

We present a compiled dataset of airborne in situ measurements of aerosol and cloud microphysical properties and cloud condensation nuclei (CCN) spectra carried out during 2015-2018 as part of the 5-year North Atlantic Aerosols and Marine Ecosystems Study (NAAMES). These field campaigns target distinct cycles in the atmosphere above the annually-occurring North Atlantic phytoplankton bloom, which provide excellent opportunities to examine the influence of biogenic aerosols on CCN and clouds against a backdrop of both the presence and absence of anthropogenic pollution. Aerosol and cloud droplet number concentrations observed during November, 2015, were extremely low, while the addition of aerosol (by ~10- fold) during the Springtime increases cloud droplet number concentrations substantially. Results obtained during Fall 2017 are similar to those obtained in Spring 2016 in terms of mean aerosol loading. Meanwhile, the shape of the CCN supersaturation spectrum remains similar across all three deployments. In addition, we report the cloud droplet sensitivity to aerosol number, hygroscopicity, and cloud updraft velocity. The results of NAAMES and sensitivity of cloud droplet number to aerosol loading will be contextualized within the results of past airborne campaign targeting aerosol-cloud interactions.

7CC.14

New Particle Formation Impacting Cloud Condensation Nuclei Concentration. ANNA GANNET HALLAR, Lauren Zuromski, Ian McCubbin, Douglas Lowenthal, *University of Utah*

There are several potential underlying principles that allow aerosol nucleation to occur more frequently at high elevation sites. Previous work has shown that frequent New Particle Formation (NPF) occurs regularly (52% of days) at a remote high elevation (3210 m a.s.l.) site in Colorado, Storm Peak Laboratory (e.g., Hallar et al., 2011; Hallar et al., 2016). This new work will present a long-term climatology (2001 – 2017) of aerosol size distributions and clearly shows a seasonal dependence on new particle formation at Storm Peak Laboratory. Furthermore, using this extensive data record, an aim of this study is to demonstrate a statistically significant connection between NPF events and growth to Cloud Condensation Nuclei (CCN). Ambient CCN data Storm Peak Laboratory has been collected for the last decade. These new results suggest that NPF in this remote region are directly impacting the number of available CCN at a supersaturation relevant to orographic cloud formation.

7CD.1

Oxidative Potential of Ambient Aerosols: First Measurement over Santiago Metropolitan Area. Carolona Molina, Vishal Verma, Victor Vargas, LEIVA G. MANUEL A., *Facultad de Ciencias, Universidad de Chile*

In Chile, almost 90% of the population lives in polluted urban areas, such as Santiago Metropolitan Area (SMA, 33.5ºS, 70.5ºW), the capital of Chile. In SMA, the levels of PM often exceed national air quality standards and guidelines of the World Health Organization. The exceedance of limit values for both PM10 and $PM_{2.5}$ occurs mainly due to urban expansion, domestic heating, growth of diesel vehicles fleet, and industrial activity. The particular geographic and meteorological conditions in SMA have additional effects on air quality. The population of SMA (7 millions inhabitants) are exposed to high levels of air pollution.

It is shown that PM produces adverse effects on human health, even at low concentrations. Although the mechanisms of PM related health effects are not well understood, the most accepted hypothesis considers the PM-induce inflammatory processes by promotion of oxidative stress; as a result of over-generating reactive oxygen species (ROS) and radical species that exceed the available antioxidant defenses producing cell damage. Therefore, the oxidative potential of PM (defined as a measure of the capacity of PM to oxidize target molecules and generating ROS or other reactive species) is a good indicator of its toxicity. Despite its importance, the oxidative potential of PM has not yet been studied over SMA, as per our knowledge.

In the present work, a dithiothreitol (DTT) assay was used to measure the ROS-generation potential of water-soluble $PM_{2.5}$ and PM_{10} of 30 ambient PM samples. The results obtained show that even when the mass proportion of PM2.5 over PM10 is around 60%, the proportion in OP is 80%; indicating that the highest loss activity of DTT is contributed mainly by the fine fraction of the PM in SMA. The comparison of OP values with other cities in the world shows that the OP of SMA ambient PM is at upper end of the typical range observed for ambient PM. Finally, these preliminary results show the importance of systematically measuring the OP of PM in SMA; and even more in other polluted cities of Chile where the PM mass concentrations exceed even SMA.

Intranasal Airway Deposition of Dry Particles in Physical Models of Children and Adults during Inspiratory Flow Rates Representing Rest, Light, Moderate and Heavy Activity.

Jana Kesavan, VALERIE J. ALSTADT, Jerold Bottiger, Keith Sedberry, Beth Laube, *US ARMY ECBC*

Background: Although the potential for negative health effects from deposition of toxic particles in the intranasal airways of children makes determination of deposition in this region essential, studies of particle deposition that include exposing infants and children are not feasible. Anatomically-correct physical models provide a method for quantifying intranasal deposition of inhaled particles without direct exposure to humans. Toxic particles may be liquid or dry. However, little is known about intranasal deposition of dry particles during different activity levels within physical models of young children.

Methods: We used stereolithography and CT scans to generate anatomically-correct physical models of the head, face with nostrils and intranasal airways of a 2 and 5 year-old child and 18 year-old adult. We then quantified and compared deposition of 1-10 µm dry particles of Arizona Test Dust in the intranasal airways of the models during inspiration only, at flow rates representing rest, light, moderate and heavy activity. Data were standardized using the impaction parameter, so that deposition in the three models could be compared.

Results: Intranasal deposition of 2.458 µm dry particles at light activity flow rates was similar for all three models. However, deposition was significantly greater in the 2 and 5-year-old models, compared to the 18 year-old model, for particles smaller and larger than 2.458 µm, during inspiratory flow rates representing rest and light activity. Deposition in the 5 year-old was greater than in the 18 year-old for all particles ≥2.458 µm during moderate activity and ≤8.977 µm during heavy activity. Deposition in the 2 year-old model was significantly greater than in the 5 year-old model for ≥4.698 µm particles at light activity flows and for all particle sizes at moderate and heavy activity. Variability in intranasal deposition for the three models was reduced when standardized in terms of impaction parameter combined with the anatomical parameters of Amin (the minimum cross-sectional area of the nostrils) and Ellipticity (the ratio of nostril length to width).

Conclusions: Intranasal deposition of dry particles between 1-10 µm may be greater in 2 and 5 year-old children, at rest and during light activity, compared to adults, and may be greater in 2 year-old children, compared to 5 year-olds, during moderate and heavy activity. These results suggest that the intranasal airways of 2 and 5 year-old children may be at risk for detrimental health effects from increased exposure to toxic dry particles during nasal breathing, compared to adults. Studies in additional models based on similar age children are needed to confirm these findings.

Investigating the Effects of Cookstove Emissions on Ocular and Cancer Cells. BEDIA KARAKOCAK, Sameer Patel, Nathan Ravi, Pratim Biswas, *Washington University in St Louis*

2.7 billion people burn solid fuels for cooking and heating using stoves, with major health consequences. Solid fuel combustion emissions increase the prevalence of illnesses such as chronic obstructive pulmonary disease and lung cancer; however, their effect on eyes is underexplored. In this novel study, three healthy ocular cell lines (corneal, lens, and retinal epithelial cells) and a cancer cell line were exposed to gas and liquid phase combustion emissions from applewood and coal.

In the first part of the study, three healthy ocular cell lines underwent controlled exposures on three separate occasions to filtered air, applewood, and coal smoke from incomplete combustion for one hour in a controlled chamber. In the second part, particles formed as a result of biomass combustion were collected on a filter. The ocular and cancer cells were then exposed to the filter extracts for 24 hours.

The viability of the cell lines exposed to stove emissions was assessed by measuring real-time cell attachment behavior and cell metabolic activity. Reactive oxygen species (ROS) generation was also quantified. For both phases, the results indicated that coal emissions compromised the viability of ocular cells more than applewood emissions. Interestingly, the cancer cells, although their viability was not compromised, generated 1.7 to 2.7 times more ROS than healthy cells. This acute exposure study provides compelling proof that biomass combustion emissions compromise the viability of ocular cells and increase ROS generation. The increased ROS generation was fatal for ocular cells, but it promoted the growth of cancer cells.

Reactive Oxygen Species of Ambient Water-soluble PM2.5 in the North and Northwestern China: Contrasts in Concentration and Sources. YAQING ZHOU, Rujin Huang, Junji Cao, *Key Laboratory of Aerosol Chemistry and Physics, IEECAS*

$PM_{2.5}$ pose an unequivocally health problem, which may penetrate deeply into the human respiratory system and leading to oxidative stress. China has suffered severe haze problems during winter in recent years. So far, a direct causative link between particle properties and adverse health effects and the main sources of these toxic components is currently lacking. In this study, the ROS concentration, link between chemical components and ROS, source apportionment of particle-bound ROS are reported in three major cities in north and northwestern China. The average particle-bound ROS concentration in Beijing, Xi'an, Shijiazhuang during 2013 winter were measured using DCFH method, which were 0.43±0.38, 0.89±0.55 and 0.76±0.46 nmol $H_2O_2 \bullet m^{-3}$, respectively. The mass ROS efficiencies of three cities were 0.005, 0.005 and 0.002. Xi'an has the largest ROS concentration and mass efficiency. Different level of water-soluble metal seems to have obvious influence on ROS that high water-soluble Fe may accelerate the formation of ROS, and high water-soluble Cu may reduce the increase of ROS. Based on preliminary source apportionment result, vehicle emission has the largest contribution (40%) to ROS, and biomass burning increase obviously when air condition changed from cleans days to extreme pollution days.

A New Risk Grouping Concept for High Aspect Ratio Materials - The Fibre Dustiness Test by Vibro-Fluidization.

ELISABETH HEUNISCH, Dirk Broßell, Volker Bachmann, Nico Dziurowitz, Carmen Thim, Daniela Wenzlaff, John Schumann, Kerstin Kämpf, Asmus Meyer-Plath, Sabine Plitzko, *Federal Institute for Occupational Safety and Health (BAuA)*

Introduction High aspect ratio materials (HARM) like carbon nanotubes (CNT) exhibit material properties that enable innovative applications but also raised concerns about potentially harmful effects to humans due to their asbestos-like morphology. Control banding by grouping of HARM by hazard- and exposure-related properties is a promising approach to risk assessment and risk mitigation for a large family of materials. Such grouping requires identifying dust release quantifying properties that enable a differentiation of HARM with low, moderate or high dustiness together with information on dust morphology.

Methods We have developed a dustiness test for powdery HARM and studied it for a broad range of CNT materials. Fibre dustiness testing was performed by vibro-fluidization that passes a low-volume airflow through a vertically vibrating powder column. Vibration allows overcoming adhesive forces between powdery agglomerates that would otherwise hinder fluidization. The vibro-fluidization method allows controlling airflow, vibration amplitude and frequency. The released aerosol was monitored and collected downstream to study the dust generation process and to determine process and material-related parameters. All collected samples were analysed by means of scanning electron microscopy (SEM) to obtain detailed information on the dust composition and its morphology.

Results and Discussion We performed dustiness tests on 15 different types of MWCNTs. The results allowed to develop a material ranking scheme based on the emission propensity for different morphological dust classes and to define distinct emission bands for low, moderate and high dustiness. SEM-based morphological analysis, of more than 500 emitted objects per material, enabled us to rank HARM according to their propensity to emit fibres in individual or agglomerated form. We also measured pair-wise distributions of diameter and length to identify and quantify potentially rigid fibres and those matching the WHO definition for potentially hazardous fibre geometry with a self-developed software. The obtained results form the basis of our proposed new grouping strategy for control banding that classifies HARM using a risk matrix. The matrix considers both intrinsic material and process-related properties such as bio-durability, toxicity as well as dustiness, grade of agglomeration and presence of hazardous WHO-fibres.

Oxidative Potential of Ambient Fine Aerosol during Intense Biomass Burning over the Indo-Gangetic Plain-India. ANIL PATEL, Rangu Venkata Satish, Atinderpal Singh, Darshan Singh, Neeraj Rastogi, *Physical Research Laboratory, Ahmedabad, India*

Emissions from biomass burning (BB) are dominant global source for carbonaceous aerosol and gases in the atmosphere. On regional scale, the emission budget reveals that nearly 400 Gg of particulate organic carbon (OC) are produced per year from post-harvest paddy-residue burning emissions in the Indo-Gangetic Plain (IGP). Particulate matter (PM) from BB, mostly comprised of fine carbonaceous aerosol, may have significant impact on regional air quality and human health as they are capable of penetrating into the alveolar region and might absorbed into the blood stream of the human body that may cause various cardio-pulmonary diseases. A widely accepted proposed mechanism related to the effect of PM on human health is that inhaled ambient PM generates reactive oxygen species (ROS), which further cause cellular damage and induce oxidative stress in human. Capacity of PM to generate ROS is termed as their oxidative potential (OP). A variety of cellular and acellular assays have been developed to quantify different aspects of PM-induced oxidative stress based on the possible mechanistic route linking aerosol chemistry to health.

In present study, daytime and nighttime $PM_{2.5}$ (PM with aerodynamic diameter less than or equal to 2.5μm) samples (n = 69) were collected on tissuquartz filters using high volume air sampler during October–November, 2014 over a semi-urban site (Patiala: 30.2°N; 76.3°E, 250m amsl) in the IGP, India. In parallel, the mass concentration of black carbon (BC) was also determined with seven wavelengths Aethalometer. Study period covers the ambient air conditions of the study region before, during and after a large scale post-harvest paddy-residue burning to assess the effect of biomass burning emissions on the OP of aerosol. Filter samples were analyzed for major anions, cations, organic carbon (OC) and elemental carbon (EC), water soluble organic carbon (WSOC), sugars including levoglucosan, and trace metals. Further, a widely used dithiothreitol (DTT) assay was used to measure the OP of soluble ambient $PM_{2.5}$.

Volume normalized OP (OP m^{-3}) is found to be highly correlated ($R^2 \geq 0.70$, $p<0.05$) with many BB markers such as OC/EC, K^+/EC, BC_{370}/BC_{880}, and levoglucosan, which attests that observed OP is mainly due to species emitted from BB. OP m^{-3} exhibited a positive significant correlation with ambient $PM_{2.5}$ mass concentration during paddy-residue burning period ($m=0.037$, $R^2=0.78$, $p<0.05$) with ~ 2 times higher slope compared to that reported for winter (Jan-2014, $m=0.017$, $R^2=0.44$, $p<0.05$) from the same site. It is attributable to dominant contribution of species from BB to $PM_{2.5}$ during study period, which should have higher OP. However, mass normalized OP (OP μg^{-1}) was found to be increasing during post-burning period, which suggests that the aging and/or atmospheric processing of PM species from BB increase their OP. Further, OP μg^{-1} is found to be significantly correlated with ratio of WSOC to secondary inorganic aerosol (SIA) in daytime samples collected during paddy-residue burning ($m=25$, $R^2=0.59$, $p<0.05$, $N=16$) with ~ 5 times lower slope than that observed during winter 2014. WSOC during winter was reported to be predominantly of secondary origin whereas during this study, it was mixture of primary (from BB) and secondary sources. This observation suggests that WSOC formed through secondary processes are more DTT active than those emitted directly from primary sources. Such studies have implications in understanding the role of PM from BB emissions on air quality and atmospheric chemistry over a given study region, and designing appropriate mitigation strategies.

Identification of Toxicity Parameters Associated with Combustion Produced PM2.5 Surface Chemistry and Particle Structure by in Vitro Assays. RANDY VANDER WAL, Madhu Singh, Patricia Silveyra, Joshua Muscat, *The Pennsylvania State University*

Introduction: The International Agency for Research on Cancer (IARC) has labeled diesel exhaust as carcinogenic within class 1. While the mechanism(s) by which soot causes the adverse health effects are not known, a great deal of these harmful effects relate to its ability to cause oxidative stress. Thus, oxidative potential, expressed through reactive oxidative species concentration, can be used as a good estimate for its reactivity and toxicity. Accordingly, physical structure and surface chemistry become surrogate measures of its oxidative potential as together they determine the redox properties and polar/acidic character. Based on this premise, we are testing the role and impact of soot structure and surface chemistry upon interaction with bronchial and alveolar epithelial cells. The proposed project's goal is the identification of toxicity, oxidative, and pro-inflammatory factors in combustion produced soot arising from using alternative fuels, by studying the particles directly instead of studying compounds adsorbed on (and removed from) the soot particles. Model soots with tailored surface chemistry, and specific particle physical structures are being tested for toxicity, oxidative stress markers, effects of lung inflammation and and signaling pathways using cell culture bioassays, as well as protein carbonylation and DNA damage marker assessment.

Methods: An epithelial cell line (BEAS-2B) was incubated with lab-generated carbon (nascent, nitric acid-treated, and ozone-treated carbon) for 6 hr. and 24 hr. incubation times, at different concentrations (0-100 µg/mL). After incubation, we measured cell viability using the MultiTox-Fluor Multiplex Assay. In addition, we extracted RNA and protein from cells to evaluate expression of inflammatory cytokines (IL-1b, IL-6, IL-8) and genes related to the inflammatory response and oxidative stress (TLR4, CCL2, MMP1, and NRF2).

Results: Treatment of carbon particles with nitric acid and ozone resulted in differential oxygen and carboxylic acid content in the $PM_{2.5}$ surface. In BEAS-2B cells, an inverse relationship of cell viability and $PM_{2.5}$ treatment concentration was observed at both time points assessed. Of the three $PM_{2.5}$ preparations, BEAS-2B cells exposed to nitric acid-treated carbon resulted in the largest decrease (89% and 96%) of cell viability after 6 hr. and 24 hr., respectively, indicating that both carboxylic acid and oxygen content of the particle surface strongly contribute to $PM_{2.5}$ toxicity. Additional results showed an increase in gene expression of the inflammatory cytokines IL-1b, and IL-6, and the oxidative stress markers TLR4 and NRF2 at higher concentrations of PM2.5 exposure (25-100 µg/mL).

Conclusion: In summary, exposure of different types of particulate matter to lung epithelial cells increases inflammatory responses, with different effects associated with soot components such as particle surface chemistry. Future experiments will determine how functional groups in the $PM_{2.5}$ surface chemistry affect the activation of the observed inflammatory response, and decrease in cell viability of lung epithelial cells.

Near-Roadway Effects on the Progression of Alzheimer's Disease. KEITH BEIN, Christopher Wallis, Xiao-San Luo, Kelley Patten, Anthony Valenzuela, Elizabeth Berg, Jill Silverman, Pamela Lein, Anthony S. Wexler, *University of California Davis*

Recent epidemiological studies have linked traffic-related air pollution (TRAP) to increased risk of Alzheimer's disease (AD). In addition, in vivo and in vitro studies have shown that individual components of TRAP can alter neuroinflammation, increase neurotransmitter levels, and increase neurogenesis. However, TRAP exposures are challenging to reproduce in laboratory settings, and the mechanisms by which TRAP leads to Alzheimer's-related cognitive deficits remain unclear. To address these issues, we exposed male and female wildtype and transgenic Fischer 344 (TgF344-AD) rats to real-time TRAP, using an exposure facility that samples air directly from a highway tunnel in the Bay Area of California used by both light- and heavy-duty vehicles. TRAP and filtered air (FA) PM samples were collected for 24 hours once every third day, and a subset of these were analyzed for particulate matter mass, organic and elemental carbon composition, and elemental composition. Gas phase samples were collected monthly on sorbents and analyzed for molecular organics. The goal of this project is to test the hypotheses that exposure to TRAP triggers inflammatory responses in the brain that initiate, accelerate or exacerbate progressive AD pathology and cognitive dysfunction, and that the response to TRAP varies depending upon sex, age, and expression of AD susceptibility genes. To test these hypotheses, we are quantifying cytokines in the periphery and brain, neuroinflammation, neuropathology, and cognitive impairment in rats genetically predisposed to AD and their wildtype littermates exposed to TRAP or FA beginning at postnatal day 28.

7CD.10

Evidence of Atmospheric Secondary Transformation of Transition Metals and Impact on Particle Oxidative Potential.

ZHI NING, *City University of Hong Kong*

Exposure to fine Particulate Matter (PM2.5) has been linked with various adverse health effects. Particle bound metals, especially transition metals, are hypothesized to initiate respiratory disease and trigger systemic inflammatory disease response. Understanding the role of metals in PM induced health effects is key to mitigate the impact of air pollution and protect public health. Iron is the most abundant PM transition metals from various sources including road dust, traffic, industrial and ship emissions. Many research studies have shown positive association between water soluble iron and the generation of reactive oxygen species (ROS) as the pathway to oxidative stress. However, the two different oxidation states of ferrous (Fe(II)) and ferric (Fe(III)) can be inter-converted in which photoreduction of Fe(III) to Fe(II) theoretically participates in a catalytic cycle to produce toxic hydroxyl radicals (·OH) and Fe(II) can also be oxidized to Fe(III) by molecular oxygen to generate superoxide anion O2- while Fe(III) plays an important role in various redox reactions. This study combines both real world field investigation to provide evidence-based knowledge on the particle bound water soluble iron speciation, and laboratory investigation to evaluate the impact of atmospheric processing and aging on the conversion between Fe (II) and Fe (III). Clear evidence was found in the atmospheric transformation of the transition metal of iron during day and evening times, same with the laboratory controlled UV exposure experiments. Controlled tests and spike tests with addition of ironic components showed their positive contribution to the overall oxidative potential of aerosols. The reactive oxygen species generated from the fresh and secondary formed aerosols also showed clear difference suggesting the strong impact of transformation of transition metals on the health implications. This study is one of the first investigations of its kind, and we expect the results will form the basis to better understand the relation between particle metals and health effects.

7CD.11

Generating Biodiesel and Fossil Diesel Exhaust Particles with Varied Physico-Chemical Properties for Toxicological Studies.

LOUISE GREN, Vilhelm B. Malmborg, Pravesh C. Shukla, Sam Shamun, Christina Isaxon, Per Axel Clausen, Martin Tunér, Ulla Vogel, Joakim Pagels, *Ergonomics and Aerosol Technology, Lund University, Sweden*

Introduction

Diesel exhaust (DE) is classified as carcinogenic and is suspected to play an important role in the adverse effects of ambient PM in urban areas. Candidates for toxicologically relevant particle properties include the specific surface area and surface reactivity of the solid black carbon core, the liquid organic fraction including polycyclic aromatic hydrocarbons (PAHs), and transition metals.

The use of renewable fuels such as rapeseed methyl ester biodiesel (RME) and hydrotreated vegetable oil renewable diesel (HVO) in the commercial and private transport sectors is increasing. The fuels reduce net green house gas and alter health relevant emissions compared to fossil diesel (Murtonen et al., 2009). The largest reduction of emitted PM is attributed to RME, however its oxygenated organic fraction has been linked to increased oxidative potential and higher in-vitro toxicity (Hedayat et al., 2016). The chemical composition of HVO fuel is more similar to fossil diesel , so far the knowledge of its exhaust emissions is limited.

We here describe an approach where the particle composition and properties can be varied over a wider range and in a more systematic way compared to previous studies while maintaining realistic engine operation conditions. Exhaust, from a modern heavy-duty diesel engine fueled by fossil diesel, 100% RME and 100% HVO biodiesel , was characterized and collected to be used in a n in-vivo toxicological study.

Method
